Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Foreword

My first employer, the late Gordon Carter, and a man of real wisdom, once said to me: "You won't know the meaning of 'experience' as a clinician until you have been in practice for 20 years, and then you will realise you don't have any." At the time I had no idea what he was talking about. I know now.

The longer one is in practice, the less dogmatic and certain one often becomes. Horses accumulate, which just will not fit neatly into their diagnostic buckets. Prognoses, which were once certain fact, become turned on their heads by the horse that defies the clinician's worst predictions, and comes back from injury against all the odds. Nerve blocks seem increasingly to eliminate pain from regions that were not their target, or do not abolish pain from areas that were. Radiography repeatedly shows no abnormalities in bones when magnetic resonance imaging (MRI) demonstrates gross and marked pathology.

When meeting this plethora of square circles for the first time, the previously available textbooks just made one feel even more hopeless. Nerve blocks were either not needed at all for a diagnosis because a clinician of experience did not NEED to block a horse to know where the problem was. When it WAS employed, diagnostic analgesia eliminated pain in a totally predictable and specific way. All was black and white, clear cut, and specific. This was not the world of equine lameness that I was picking my way through as a novice clinician. Was I simply doing it wrong? Or was it perhaps that there are reasons why biological systems refuse to be pigeon-holed in the neat manner we would like them to be pigeon-holed?

The first edition of *Diagnosis and Management of Lameness in the Horse* was a revelation in that respect. Here were clinicians determined to use a scientific and methodical approach to their horses, but at the same time describing all the many and varied ways that diagnostic tests could mislead. Moreover, here were clinicians who were even admitting to sometimes not making a diagnosis at all.

The feeling of excitement one experienced in realising, as one read succeeding chapters, that other people were groping slowly forward in the same dark tunnel, with the same dim candles as one was oneself, was invigorating. Mike Ross and Sue Dyson redefined the equine lameness textbook in a way that was truly new, breathtaking in its breadth and depth of coverage, and for the first time addressing the fact that horses who perform in the many different disciplines we serve have many different clinical problems. Even horses with the same problems may be managed differently. For the first time each of our specialties was addressed in a clinically relevant manner, often by people at the height of their clinical powers. Although no substitute for experience itself, this massive accumulation of wisdom was put into the public domain, available to novice and expert alike. The very title uses the word

"management," acknowledging that although we cannot always expect a total cure with treatment, the horse may be useful or may compete with careful management nonetheless.

Isaac Newton once said "If I have seen a little further than others, it is only because I have stood upon the shoulders of giants." We are in a golden age of equine diagnostic imaging, with ultrasonography, radiography, scintigraphy, computed tomography, and MRI all in frequent clinical use, allowing us to define with greater clarity the damage that produces the pain and therefore lameness in our patients. So who were those giants to whom we collectively owe so much? Many were mentioned in the Foreword to the first edition of this book, and some are omitted here solely through lack of space rather than respect. Ron Genovese and Norman Rantanen set up the field of ultrasonographic examination in the horse for us all to enjoy. In radiography, almost every useful paper in my formative years seemed to have the name Tim O'Brien on it somewhere. He, along with Bill Hornof and other colleagues at the University of Davis, California, United States described the oblique images of the third carpal bone, the flexed image of the distal aspect of the third metacarpal bone, and the "skyline" flexor surface image of the navicular bone, so valuable and yet now taken for granted.

A single issue of *Veterinary Clinics of North America* devoted to Racetrack Practice published in 1990 advanced our knowledge vastly in the field of lameness in this field thanks to all of the authors, but from my own perspective, especially from the work of Roy Pool and Greg Ferraro, masters of their craft. Roy Pool was able to highlight the dramatic role that chronic, daily, repetitive microdamage played in the development of many "spontaneous" fractures. The days of the single misstep as the cause of the majority of fractures were becoming numbered, and even the acute carpal "chip" was shown to be anything but acute in most horses, certainly in terms of aetiology. I was fortunate in my early career to share a month "seeing practice" with Greg Ferraro, Tim O'Brien, and that pantheon of orthopaedics, Larry Bramlage, and that month altered the way I worked for the remainder of my career. There cannot be three people of greater wisdom, clinical skill, and willingness to share that expertise with others on the planet. As an equine orthopaedic surgeon also of great tact and humility (something of an oxymoron), Bramlage has also been a wonderful ambassador to our profession. He, along with Wayne McIlwraith, Dean Richardson, Ian Wright, and David Nunamaker, have added greatly to our knowledge of lameness from a surgical perspective.

Scintigraphy was perhaps the biggest diagnostic leap forward for the racehorse, and has been useful in most other disciplines. This was only because of the dedication and willingness to share openly their knowledge with

others by its founding fathers, and their able technicians. These include Gottlieb Ueltschi, Bob Twardock, Mike O'Callaghan, and one of the editors of this book, Mike Ross, all giants indeed, to whom we should be grateful.

In the field of MRI and diagnostic analgesia, the other editor of this book has made an enormous contribution. The name Sue Dyson has become a by-word for elegant, meticulous, probing studies by her and her team at the Animal Health Trust, Newmarket, England, carried out with great scientific integrity, documented in detail and published for all to share. She has made a unique and lasting contribution to studies of equine lameness, and the interlocking problems of the atypical consequences of the use of diagnostic analgesia, without in any way diminishing their importance as the foundation stone of lameness work—in fact, just the reverse. In MRI studies she joins other giants such as Russ Tucker and Rachel Murray who have opened up and explained this fascinating technique to the equine practitioner, and whose insights into the structural damage that leads to pain and consequently lameness have added so much to the various sections of this new edition.

We must not forget the value of thorough clinical examination. The previous generation of lameness clinicians had no recourse to the advanced imaging modalities listed above, but they nevertheless diagnosed and treated horses, many of which returned to a useful life. We can argue that their presumptive diagnoses may have been incorrect in the light of what we know now, but they accumulated experience of which factors worked in restoring a horse with a specific set of clinical signs to soundness. Lameness practice, as pointed out in the first edition, is both an art and a science. The science is often dogma, a “best fit” for the current facts, but the art is a more continuous and constant tradition that many of the contributors to this second edition uphold and in turn pass on. An example of this would be pain which is abolished by both proximal palmar metacarpal (subcarpal) nerve blocks and later also by intraarticular analgesia of the middle carpal joint in a Thoroughbred racehorse. Many of these horses have slight thickening, possibly mild tenderness to palpation of the proximal suspensory ligament, and increased severity of lameness after carpal flexion, but no clinically significant lesion on ultrasonographic examination or radiography. For my generation, MRI is an available option, and in these circumstances one often finds a combination of injuries to the most proximal part of the suspensory ligament or its bone origin, the origin of the accessory ligament of the deep digital flexor tendon, the palmar carpal ligament, the interosseous ligaments between the third

and second and fourth metacarpal bones, or in areas of the third and radial carpal bones simply not visible radiologically. Ray Hopes, my mentor, previous employer, and now good friend, who founded the racing division of the Rossdale practice in Newmarket, England could not have recognised these injuries. Did he diagnose the condition of horses with the blocking history we have outlined? Yes he did. Did he treat these horses and successfully manage their return to training and competition? Very much so. He could not have known the true nature of the lesions. No-one in that era could have done so, but he accumulated enough wisdom and experience to know what one had to do, in terms of rest, therapy, and rehabilitation, to get those horses back to work, a legacy we still employ to the same end point today, possibly for different reasons and with more knowledge now of why it works.

This second edition is not simply a reprint with minor changes to some sections. Every single chapter has been updated, some such as “The Tarsus” and “Navicular Disease” virtually rewritten; such is the avalanche of new knowledge that has come our way in the intervening 8 years. Almost all of the figures have been replaced with better quality digital images that significantly enhance the text. In addition some subjects not previously covered have now been included. Alan Wilson and Renate Weller contribute a new Chapter, “The Biomechanics of the Equine Limb and Its Effect on Lameness.” Whilst it may sometimes seem to us that all horses are lame, the majority of course are not. Careful study of biomechanics, particularly in the context of conformation and shoeing, may help us understand why one horse goes lame when its cohort group remains sound under the same exercise regimen.

There are certain seminal textbooks that become so widely known, used, and respected in their field that the title of the book becomes subsumed by the name of the author in the public mind, as succeeding editions are updated and published. Sisson (anatomy), Lehninger (biochemistry), and Roitt (immunology) are books of this type. With this second edition, “Ross and Dyson” is about to join that list. It has become THE textbook on equine lameness. Clinicians certainly do not write textbooks with financial rewards in mind, or if they do, they have been wickedly deceived by their publishers! One has to hope that the knowledge that entire generations of equine practitioners will be enthralled, educated, and engaged by this masterly work will serve as just reward.

Rob Pilsworth
Newmarket, England
January 2010

Second Foreword

The production of veterinary texts addressing lameness in the horse has been very enlightening and, needless to say, a valuable tool to the equine practitioner. It is remarkable that the majority of the veterinary texts have been formulated within the past 50 years. Naturally, this incentive to produce texts has come from the resurgence of the number of horses in the United States. In the late 1920s, the number of horses in the United States was reported to be approximately 27 million. *Dollar's Veterinary Surgery* was a text of note during this period, first being published in 1912; the second edition appeared in 1920, the third in 1937, and the fourth in 1950. In the Preface to the Fourth Edition, JJ O'Connor, MRCVS, who edited the third and fourth editions, made note of the nine additions of new material it contained. The last of the additions was "the examination of horses as to soundness" (approximately 200 pages). This time period is significant because the number of horses in the United States had dramatically dropped to approximately 750,000 by 1957. This precipitous drop in the number of horses prompted a general prediction that if the practice of equine veterinary medicine was not going to completely disappear, it would be a very limited part of veterinary medicine. Consequently, research into equine issues of note was very limited, if at all, and publications of scientific articles relevant to horses were also very limited. Basically no texts were produced after Dollar's fourth edition until the early 1960s; however, in the 1950s a small number of devoted veterinarians, both practitioners and college professors, were diligent in pursuing the cause for the diagnosis and treatment of the lame horse. At the same time, there was a reversal in the decline of the number of horses in the United States. This stimulated more interest in equine veterinary medicine and spawned the resurgence of written material relevant to the lame horse. A reference point to this increase is the fact that the number of horses was reported to be 9.2 million (American Horse Council's DeLoitte Report, June 5, 2005). Concurrently, the American Association of Equine Practitioners (AAEP) was born; this association has served since its inception as a medium to accumulate and disseminate information relevant to the lame horse. It was through the AAEP that I became familiar with the contribution by Dr. Mike Ross and Dr. Sue Dyson.

In the first edition of *Diagnosis and Management of Lameness in the Horse*, in 2003, "Part I: Diagnosis of Lameness," "Section 1: The Lameness Examination," "Chapter 1, Lameness Examination: Historical Perspective," Dr. Mike Ross states "in the mid to late 1900s Adams had the most profound influence by his teachings and writings." He further references O.R. Adams' 1957 "Veterinary Notes on Lameness and Shoeing of Horses" becoming the classic textbook, *Lameness in Horses*. As a graduate of Colorado State University in 1957, I consider it to be one of the

privileges of my veterinary career to have been a student of Adams, a part of his notes in 1957, and then a very close friend. Until Adams' first edition of *Lameness in Horses* was published, his notes were invaluable to me. The historical perspective by Dr. Mike Ross echoes my thoughts regarding the assessment of the texts and information relevant to the study of the lame horse, including his reference to those that have influenced the molding of modern lameness detectives. An insight into the history of the printed material directed toward the diagnostic and therapeutic management of the lame horse allows a better insight into the appreciation of the modern printed texts relevant to this subject. Specifically the editors, in the first edition, presented the contents throughout the text in a very logical manner, providing excellent approaches to the resolution of the lame horse's problems. The contents reflect the objective thinking of both editors and their contributors. The first nine chapters are vital to the lameness examination; the CD-ROM component enhances this segment in an extremely useful manner. When those principles are applied, then the logical application of the material in Chapters 10, 11, 12, 13, and 14 will follow as necessary.

Paramount to lameness management is the identification of the pain site causing the lameness. When that has been accomplished, the direction to be taken to resolve the issue will be set. Certainly the material provided in Section 2 of Part I will be utilized as the next step in arriving at the specific site of the infirmity; however, when the factors described in Section 1 of Part I are carefully followed, resolution of the problem may not require the employment of diagnostic imaging. The approach outlined by Section 1 Part I serves as a reminder that the modern "lameness detectives" are provided with the faculties of observation, palpation, and a brain. When used properly, these will facilitate a diagnosis without the necessity of further diagnostic modalities; however, when necessary, diagnostic imaging is vital to the identification of the pain-producing lesions. Certainly the advancements in the diagnostic imaging modalities have enhanced our ability to arrive at a more precise diagnosis with the obvious benefit of arriving at a more complete treatment and prognosis. The second edition contains the revelation of more diagnostic detail than was available in the first edition.

The editors have clearly provided a logical progression by structuring the contents of the text with the foot (Part II) following the general remarks regarding the diagnosis of lameness (Part I). Incorporation of recent discoveries of Robert Bowker, Christopher Pollitt, the editors, and others involved in studies of the foot will be useful information. The assessment of the information and input by the editors with their clinical experience should prove to make the understanding of the foot even more applicable to

management of the information encountered in arguably the most common site of lameness in the horse.

The flow of the text continues in a manner in which the diagnostician should proceed to arrive at an informed solution to the lameness problem. The incorporation of the axial skeleton (Part V) in the first edition continues to remind the equine practitioner that its evaluation is very much a part of the assessment of the lame horse. Certainly in my career the axial skeleton has gone from being of very little consideration to its importance today. The inclusion of recent approaches to the diagnosis of axial skeleton issues is going to be another welcomed event.

The contributions to lameness other than those involving the skeleton and articulations as outlined in Parts VI, VII, and VIII of the first edition are updated as well. Certainly, there have been several new therapeutic modalities available for the management of lameness since the first edition. Again, the experience of the contributors and the editors will provide welcome information. Since publication of the first edition, the value of complementary therapy in equine practice continues to evolve, to demonstrate where it fits in Western medicine and the management of the lame horse.

Part V, "Lameness in the Sport Horse" in the first edition provided valuable information into not only the differences between the types of lameness encountered in various

athletic endeavors of horses, but also those differences encountered throughout varying geographic locations. There is a difference in the degree of lameness from navicular disease and other soft tissue causes of palmar foot pain at 1609 meters compared with those at sea level.

The CD-ROM component of the first edition has evolved into the website feature of the second edition. The 47 narrated videos of equine lameness provide not only insight into evaluating the more common types of lameness, but also provides examples of unusual cases that escape accurate description by the written word.

I am confident that this second edition of *Diagnosis and Management of Lameness in the Horse* will be a major addition to the libraries of equine practitioners around the world. As a recipient of the contents of the texts that have been produced over the past years, I am extremely grateful and appreciative of the time and effort the editors, Mike W. Ross and Sue J. Dyson, and the contributors have put into this text. Not only does this information and the information provided by other similar literature aid the practitioner, but it has materially improved the health and welfare of the horses we care for.

Marvin Beeman

Littleton, Colorado, United States

January 2010

Preface

The second edition of *Diagnosis and Management of Lameness in the Horse* has been substantially revised. The knowledge that has been accrued through the clinical application of magnetic resonance imaging (MRI) and, to a lesser extent, computed tomography has revolutionized our understanding of many conditions, most especially those of foot pain. This is reflected by the greatly expanded section on the foot. In each chapter we have tried to reflect both our own advances in knowledge and those of our authors, as well as what has been published in the literature. Relevant new references are cited. We have introduced many new images, most acquired digitally and therefore of superior quality, but space constraints restrict what can be included. Some original illustrations reflecting unique conditions have been preserved.

Some chapters have been written by different authors. This did not necessarily reflect that we were unhappy with the original authors, but rather that we wanted a different approach in some instances. We have again added editorial comments to some chapters when our personal experiences differed greatly from those of an author.

As we work daily with lame horses our own knowledge and experience continue to grow. It is also inevitable that between submission of the material for the second edition to the publishers and the book's publication, new literature has been published. Therefore although this new edition

reflects as far as possible state-of-the-art information, there are inevitably a few minor omissions.

A major criticism of the first edition of the book was the quality of the binding. We were delighted to learn that the book was being used to such an extent that the bindings failed. We suspect that the second edition, being bigger, unfortunately may also suffer in the same way.

We continue to learn by looking and seeing and encourage readers to watch the videos on the companion web site and listen to the commentaries, which we believe provide a fundamental background to the art of assessing a lame horse. We continue to hold the philosophy that a comprehensive clinical examination, combined with a logical approach to investigation, usually results in an accurate diagnosis, while acknowledging that a minority of horses elude diagnosis. There is a danger that with advances in imaging technology there is a temptation to utilize these tools excessively. We must remember that in many horses a correct diagnosis can be achieved by accurate palpation, observation, and use of diagnostic analgesia, combined with radiography and ultrasonography.

PREFACE—COMPANION WEB SITE

WWW.ROSSANDDYSON.COM

When approached with the idea of developing the first edition of *Diagnosis and Management of Lameness in the Horse* we immediately determined that having video segments to accompany the text was a necessity, a way of providing moving figures to teach the fundamentals of the lameness examination during movement. At that time there were few textbooks with accompanying digital media and it was necessary to convert to digital format existing analog video footage. We then added newly acquired digital video segments to create the 47 individual files used in the CD-ROM that accompanied the first edition. It was not our intent to capture on video each and every nuance of the lame horse. We did, however, feel strongly in presenting the fundamentals of the lameness examination and the gaits and movement of the normal horse, and to contrast movement with the horses that have pain causing lameness, neurological abnormalities, mechanical deficits, and in brief esoteric gait disturbances. The art of the lameness examination during movement was captured.

Although our views are similar in determining the end result of our examination during movement, we differ in our visual appraisal of the lame horse; for instance, Sue sees more vividly the downward movement of the pelvis when a horse with hindlimb pain causing lameness is in motion, whereas Mike sees the upward movement during a different portion of the stride. These differences and the different venues at which we complete our lameness examination are thoroughly explained in the narration.

Examples are given of horses with unilateral and bilateral forelimb lameness, some with pain originating from common locations such as the foot or lower forelimb, while in others we contrast movement of these horses with those with pain emanating from the upper forelimb. Unilateral and bilateral hindlimb lameness is demonstrated and the concept of hindlimb lameness causing a head and neck nod—a situation during which a lameness diagnostician can confuse hindlimb with forelimb pain—is demonstrated in several video clips. The effect and use of circling a horse during lameness examination, a useful maneuver used to exacerbate lameness, is shown in horses with forelimb and hindlimb pain causing lameness. Concurrent forelimb and hindlimb lameness, the effect of a rider, and gait restriction as a result of thoracolumbar and sacroiliac

region pain are demonstrated. Four horses with neurological gait abnormalities ranging from obvious to subtle, six horses with classic mechanical gait deficits causing lameness, and, finally, esoteric causes of gait abnormalities are shown.

Listed below is the table of contents of the narrated video segments included in the web site accompanying the second edition of Ross and Dyson's *Diagnosis and Management of Lameness in the Horse*. Using technological advances developed in the 8 years since the first edition was published we have changed the appearance of the media and improved its efficiency and utility. We have chosen to retain the original video segments and narration, feeling strongly that we have captured the essence of the lameness examination during movement and demonstrated the numerous principles of the lame horse. We debated endlessly whether to expand and include many more examples, to discuss flexion tests, to describe responses to local analgesic techniques and all the associated nuances, and to describe the many different clinical manifestations of pain arising from specific areas. Ultimately we decided not to, but we encourage readers to think about their own experiences and to share these with others.

The video segments, moving figures, have been numbered from 1 to 47, and in the right margin of the text, when appropriate, we have printed an icon  referring the reader to one or more of the video segments included in the accompanying web site we feel will be helpful to visually evaluate a horse during movement.

TABLE OF CONTENTS OF COMPANION WEBSITE

Normal Gait

1. Gait of a normal horse when evaluated in-hand and while lunged
2. Gait of a normal horse while ridden

Unilateral Forelimb Lameness

3. Left forelimb lameness
4. Right forelimb lameness
5. Unilateral forelimb lameness resulting from upper limb pain
6. Unilateral forelimb lameness resulting from upper limb pain

Bilateral Forelimb Lameness

7. Bilateral forelimb lameness worse in the right forelimb

Effect of Circling on Forelimb Lameness

8. Right forelimb lameness
9. Bilateral forelimb lameness
10. Characteristics of carpal region pain

Hindlimb Lameness without a Head and Neck Nod

11. Left hindlimb lameness in a horse with stifle pain
12. Left hindlimb lameness in a horse with bilateral suspensory desmitis
13. Right hindlimb lameness in a horse with peritarsal soft-tissue injury
14. Right hindlimb lameness
15. Left hindlimb lameness, effect of the pace and trot during lameness examination

Hindlimb Lameness with an Associated Head and Neck Nod

16. Severe right hindlimb lameness from pain associated with fracture of the central tarsal bone
17. Severe left hindlimb lameness
18. Right hindlimb lameness as a result of severe osteoarthritis of the medial femorotibial joint
19. Severe left hindlimb lameness

Bilateral Hindlimb Lameness

20. Bilateral hindlimb lameness and plaiting while trotting
21. Bilateral hindlimb lameness exhibited as a reluctance to work

Effect of Circling on Hindlimb Lameness

22. Right hindlimb lameness and toe drag
23. Toe dragging while circling
24. Right hindlimb lameness worse going to the right

Concurrent Forelimb and Hindlimb Lameness

25. Left forelimb and left hindlimb lameness
26. Left forelimb and left hindlimb lameness in a Standardbred racehorse
27. Left hindlimb and right forelimb lameness causing a "rocking-type" gait
28. Left hindlimb and right forelimb lameness in a trotter before and after low plantar diagnostic analgesia
29. Bilateral hindlimb and mild forelimb lameness in a Thoroughbred racehorse with mal- or nonadaptive subchondral bone remodeling

Other Aspects of Hindlimb Lameness

30. Hindlimb lameness while ridden
31. Gait restriction from thoracolumbar pain
32. Gait restriction from sacroiliac region pain

Neurological Gait Deficits

33. Gait deficit in a horse with a cervical spinal cord lesion
34. Hindlimb ataxia and right shoulder instability
35. Hindlimb weakness
36. Gait deficit in a horse with cervical stenotic myelopathy

Mechanical Gait Deficits

37. Fibrotic myopathy
38. Stringhalt
39. Shivers
40. Upward fixation of the patella
41. Fibularis (peroneus) tertius injury in a mature horse
42. Fibularis tertius avulsion injury in a foal

Esoteric Gait Abnormalities

43. Right hindlimb gait abnormality
44. Running type of hindlimb gait
45. Aortoiliac thrombosis
46. Left hindlimb lameness and gait deficit in a horse with gastrocnemius origin injury
47. Idiopathic shortening of the cranial phase of the stride in a right hindlimb

Acknowledgments

Just as when we wrote the first edition of *Diagnosis and Management of Lameness in the Horse*, we owe tremendous gratitude to our co-authors, many of whom have updated their original chapters, updated and changed figures, and continued to provide us with their unique lameness experiences. In most instances we have returned to the original authors for this second edition, but found it necessary to change authors and to proceed in a new direction with some of the chapters. We give wholehearted thanks to previous authors not included in this edition and welcome our new contributors. Writing textbook chapters is often a thankless job, with little remuneration, and we appreciate the efforts of all who have contributed. In many ways the project to complete the second edition was an easier task than our previous mission, because the skeleton of the textbook, including the major subsections of the written text, remained largely the same. We are grateful to all who inspired the development of the first edition and remain indebted to their initial and continued support.

We are honored by the continued support of our friend, colleague, and co-author, Fabio Torre, who once again has provided us with inspirational cover art. Fabio's original paintings for the first edition hang with pride in each of our homes, reminding us daily of Fabio's unique contribution to the success of this book. The artwork on the cover of the second edition continues a theme dedicated to the movement of the horse, in the form of images of racing Thoroughbred and Standardbred horses in motion. Movement is an integral part of the lameness examination and is captured in still form in Fabio's artwork.

We have both continued to be blessed to work with true professionals, our co-workers, at the Animal Health Trust and New Bolton Center, University of Pennsylvania and are thankful for their continued help and support as we revised this textbook and continue our interest and work in the area of equine lameness. The constant support and professionalism of the staff at Elsevier Health Science, including Lauren Harms and Penny Rudolph, was felt throughout. We also thank Alex Baker whose high standard

of artwork we admire, and who has produced a number of new drawings for this edition.

Both of us have learned the art and science of the lame horse by dedicated and experienced lameness diagnosticians who preceded us and then taught us through their own experiences and in their own unique way. Sue continues to acknowledge the timeless support of Bill Moyer, Charlie Reid, Ron Genovese, and Midge Leitch. Sue also acknowledges the knowledge about riding, feeling, and horse management taught by David Arthur and Sheila Willcox. Mike believes strongly his career path was hugely influenced and supported by many high-quality lameness detectives, but singles out Jack Lowe, Loren Evans, and Gene Gill as particularly influential in practice, and in life.

While working on the first edition and now in the years subsequent to its publication we have had a special opportunity to learn from each other, often sharing our own unique experiences and perspectives, questioning each other, keeping each other "on their toes," occasionally with timely and critical questions, and sometimes with answers. We have often shared a podium with each other, listening to and learning first hand from each other's work. Sue has made an indelible contribution to Mike's professional life, and has become a much loved, close friend.

We both greatly appreciate the love and support given us by our families. The time commitment necessary to complete this project and the countless hours we have both invested in refining our skills and interest in the lame horse invariably took time away from our loved ones. John and Beth, our partners, we thank you for your love and willingness to provide us time to complete this edition, and for your countless suggestions and enthusiasm. Mike gives special thanks to Stone, Kennedy, and Allie for their unwavering love, and his parents. Neither one of us will ever forget the horse.

Diagnosis of Lameness

SECTION 1

The Lameness Examination

Chapter 1

Lameness Examination: Historical Perspective

Mike W. Ross

If your horse is lame in his shoulder, take off his shoes.... Young and inexperienced practitioners are quite too apt to commit the error of overlooking the examination of the foot, looking upon it as a matter of secondary importance, and attending to it as a routine and formal affair only.

A. Liautard, 1888¹

As the twenty-first century continues, the extent of change in the diagnosis of lameness in the horse depends on the individual's clinical and ideological perspective. A veritable explosion of new imaging methods such as digital radiography, computed tomography, and magnetic resonance imaging has advanced the current understanding of many musculoskeletal abnormalities. Yet to accurately assess clinical relevance, the clinician must possess a feel for the horse, developed only by careful clinical examination, a procedure that has changed little in hundreds of years. Successful detection of equine lameness does not so much require knowledge of science as it does art. Inasmuch as *art* is defined as "skilled workmanship, craft, or studied action,"² the lameness examination demands artistic experience acquired by years of clinical practice and working and learning from experienced practitioners. From Liautard's advice more than 100 years ago to that of modern lameness diagnosticians, the change in the basic skills of lameness diagnosis may be small.

Development of the artistic skills needed to become a true lameness diagnostician requires a thorough, somewhat methodical approach, much like that of a crime scene detective. I often refer to the lameness diagnostician as a *lameness detective*, and although this statement may lack sophistication, in reality, how boring would the task be if the horse could talk? To make a horse talk to you through careful palpation and observation is the essence of the

lameness examination, yet most difficult to teach. Great lameness diagnosticians likely possess this ability to read or feel the horse and skilled, workmanship-like qualities to appreciate the art in lameness diagnosis. Some, with the added ability to share this knowledge effectively, have influenced clinicians more than others simply by writing about those experiences. In the early twenty-first century, Ross and Dyson's *Diagnosis and Management of Lameness in the Horse* chronicled the exhaustive clinical experience of over 100 authors worldwide to capture the essence of the subject at that time.³ Moving figures captured as video segments on an accompanying CD and individual chapters detailing lameness distribution among different sporting activities complemented basic and advanced material.³ The book quickly became a staple of every lameness diagnostician's library. In the mid-to-late 1900s, Adams had the most profound influence with his teachings and writings. His former students and friends acknowledge his artistic talent, gained primarily from a ground-up approach to the lame horse, and his profound interest in corrective shoeing. More important, Adams' original lameness notes became his classic textbook.⁴ For most clinicians, *Lameness in Horses* represented the "lameness Bible," an excellent resource of information on equine lameness. Adams himself revised the textbook several times; most recently, his respected colleague, Ted S. Stashak, has continued in Adams' footsteps. This important work served as the foundation for learning the fundamentals of equine lameness for many during this period.

Adams was influenced greatly by the work of Dollar and Lacroix. Adams' original notes contain many drawings similar to those originally published in Dollar's *A Handbook of Horseshoeing*,⁵ a wonderful collection of drawings and excellent descriptions of shoeing, conformation, and lameness of the equine foot. Adams references the work of Lacroix⁶ in the late 1800s. In fact, until Adams' treatise on lameness, scant information about equine lameness existed. The information available in the American literature during most of the 1900s consisted of only sporadic case reports or case series in the *Journal of the American Veterinary Medical Association*. A potential explanation may lie in the importance of the World Wars or other important social events in the early-to-mid 1900s. Experience in the cavalry also may have influenced later writings in the 1900s.

Peters⁷ work detailing lameness in the Thoroughbred racehorse emphasized the importance of lameness in the racetrack practice and the most common cause of poor performance. Many problems he observed in 1939 still exist, although treatment options have expanded considerably. Early important writings included manuscripts by Churchill⁸ and Wheat and Rhode⁹ on surgical removal of proximal sesamoid bone fractures (the Churchill approach), Forsell¹⁰ on surgical management of navicular bursitis and tendonitis, and Lundvall¹¹ and later Delahanty¹² debating the subject of the existence or nonexistence of fibular fractures. An early reference of note was the surgical textbook by Frank.¹³ Originally written in 1939, with several subsequent editions, this influential and often quoted textbook contained information about numerous musculoskeletal problems and often sensational examples of common and rare abnormalities.

In the late 1800s, several informative, interesting, and entertaining textbooks about equine lameness were written, primarily by European authors. Most publications contained wonderful descriptions of lame horses, and many emphasized shoeing techniques, a mainstay in management of the lame horse both then and now. The writings of Percivall¹⁴ and Gamgee¹⁵ are particularly informative. Although a definitive reason was not provided, Gamgee observed that 42% of horses in the United Kingdom were lame, whereas only 9% of horses in Paris were lame. Disorders of the foot, many of which increased in frequency with age, were most common, and marked remodeling of the distal phalanx was seen in horses undergoing postmortem examination.¹⁵ In addition to the time-honored management technique of shoeing the lame horse, conformation and its relationship to lameness also were emphasized. In *How to Judge a Horse*, Bach¹⁶ emphasized balance, body part length and angulation, and distal extremity conformational faults. In modern day lameness examinations, conformation and its role in the development of lameness are often given cursory emphasis but remain an important part in the art of the examinations. In a chapter entitled "Horse-Docturing [sic] in the Nineteenth Century," Dunlop and Williams¹⁷ emphasized the contribution of Mayhew, described as artist, activist, and veterinary surgeon. Mayhew described and illustrated many common abnormalities of the locomotor system recognized at that time, including splints, spavin, curb, tendon sprains, and thoroughpin, most of which are still recognized today.¹⁷ Of interest, Mayhew was credited for trying "experimental" injections into inflamed areas, an obviously important treatment modality practiced today.¹⁷ Detailed descriptions of laminitis, navicular disease, and other common conditions of the equine foot were provided.¹⁷ Dunlop and Williams,¹⁷ in their treatise on the history of veterinary medicine, also detailed the transition from farriery to veterinary medicine that occurred in the 1700s, although the close association and harmonious working relationships between blacksmiths and equine

diagnosticians remain integral parts of a successful lameness management team today. In fact, "the term *veterinarian* came into use when colleges were established in different parts of Europe for improving, or rather for creating the art of treating disease in the lower animals."¹⁷ The first veterinary school was founded in France in 1761, and soon veterinary schools were formed in the United Kingdom.¹⁸

Although an exhaustive historical review might be interesting, this brief review highlights critical issues central to modern lameness diagnosis. First, the basics have not changed for hundreds of years and will likely not change in the foreseeable future. Second, with the exception of Adams' work, and more recently that of Ross and Dyson, few comprehensive reports on lameness diagnosis were written before the twenty-first century. The modern lameness detective likely has learned most from experience working with accomplished lameness diagnosticians and by word of mouth. Third, many of our most knowledgeable colleagues have not published writings but have made their contributions in day-to-day teachings in academic settings, private practice, and small gatherings at national meetings.

Since 1955 the annual convention of the American Association of Equine Practitioners has played a special role in the dissemination of information and ideas about lameness. Early meetings included a handful of practitioners, gathering and discussing equine medicine and surgery, sometimes late into the night. Much current lameness experience can be traced to these early meetings and practitioners such as Adams, Peters, Frank, Farquharson, Churchill, Goddall, Gabel, and Delahanty. Loren Evans and Howard "Gene" Gill influenced the molding of many modern lameness detectives, including me. Emphasizing the value of acquiring horse sense and spending time palpating and "learning" the horse, Gill often quotes Will Rogers, "... the outside of a horse is good for the inside of a man."

In the United Kingdom the British Equine Veterinary Association was established in 1961, providing a similar formula for dissemination of information through its annual congress and regular day meetings. The establishment of the *Equine Veterinary Journal* in 1968 provided a high-quality, refereed journal. The standard for the journal was set by the first editor, John Hickman, an astute observer of lame horses and an influence on many practitioners.

No substitute exists for careful clinical examination and observation, experience gained over many years of treating and developing a feel for the lame horse. The second edition of this textbook on lameness is once again a collection of the best and most knowledgeable lameness diagnosticians worldwide. Some are "household lameness names," whereas others are less renowned. All have one thing in common: they practice the art of lameness diagnosis and management in the horse.

Chapter 2

Lameness in Horses: Basic Facts Before Starting

Mike W. Ross

Lameness is therefore not so much an original evil, a disease per se, as it is a symptom and manifestation of some antecedent vital physical lesion, either isolated or complicated, affecting one or several parts of the locomotive apparatus.

A. Liautard, 1888¹

References
on page
1255

DEFINITION

The clinical manifestations of lameness in the horse are well known, but an exact definition is difficult. The word *lame* is an adjective, meaning “crippled or physically disabled, as a person or animal ... in the foot or leg so as to limp or walk with difficulty.”² A medical dictionary defines *lameness* as “incapable of normal locomotion, deviation from the normal gait.”³ The noun *lameness* can be, but infrequently is, used interchangeably with *claudication*, described as “limping or lameness.”³

Lameness is simply a clinical sign—a manifestation of the signs of inflammation, including pain, or a mechanical defect—that results in a gait abnormality characterized by limping. The definition is simple, but recognition, localization, characterization, and management are complex.

LOCALIZATION OF PAIN

In certain conditions, characteristic gait abnormalities allow immediate and straightforward recognition and localization of the problem. Sweeny, fibrotic myopathy, upward fixation of the patella, stringhalt, shivers, and radial nerve paresis are examples. However, similar gait deficits exist for a variety of lameness problems, complicating recognition and localization. A fundamental concept in lameness diagnosis is the application of diagnostic analgesic techniques to localize the source of pain causing lameness. The sequence of properly determining the lame leg (recognition) and then abolishing the clinical sign of lameness by use of diagnostic analgesia (localization), only to have lameness return when the local anesthetic effects abate, is essential for accurate diagnosis. In essence diagnostic analgesia establishes *clinical relevance*, a most important concept to the lameness diagnostician. With experience and under certain circumstances, this step in lameness diagnosis can be omitted. The degree of lameness, certain gait characteristics, and palpation findings allow the clinician to strongly suspect a certain diagnosis. The next step may be diagnostic imaging. For example, a racehorse with prominent lameness after training may be suspected of having a stress or incomplete fracture. Performing radiographic and scintigraphic examinations before proceeding

with diagnostic analgesia is a prudent choice. Trial and error also occasionally work and in some instances may be the preferred approach. Intraarticular analgesia can be performed in selected joints without disrupting distal-to-proximal perineural techniques later during the same examination. However, because pathognomonic signs are rare, proficiency in diagnostic analgesic techniques is mandatory for the lameness diagnostician.

BASELINE AND INDUCED LAMENESS

Baseline, or primary, lameness is the gait abnormality recognized when the horse is examined at a walk or trot in hand before flexion or manipulative tests are used. The clinician usually recognizes this abnormality by watching the horse on a firm or hard surface, while it is being trotted in a straight line. Diagnostic analgesia is used to abolish this lameness. Changing the surface or nature of the exercise by lunging, or circling the horse at a trot in hand, potentially changes the baseline lameness. The surface and exercise (gait and speed) must be consistent. In some horses no observable lameness is present at a walk or trot in hand. Lameness may be evident when the horse is ridden, and this lameness becomes the baseline lameness.

Flexion tests and other forms of manipulation are used to exacerbate baseline lameness or to induce lameness. An induced lameness is one that is observed after flexion or manipulative tests, but induced lameness may not be the same as the baseline lameness. Manipulative tests are expected to, and often do, exacerbate the primary lameness. However, flexion and manipulative tests can cause development of additional lameness, unrelated to the primary or baseline lameness, and test results must be interpreted carefully.

COEXISTENT LAMENESS

Horses often have several sites of pain, although one usually is most obvious and the cause of baseline lameness. In many horses, secondary or compensatory (sometimes referred to as *complementary*) lameness develops in predictable sites or limbs. Concomitant bilateral forelimb or hindlimb lameness is common, but horses often demonstrate more prominent clinical signs in one limb. In horses with palmar foot pain, initially pronounced single forelimb lameness that is abolished by palmar digital analgesia may be present, with subsequent recognition of contralateral forelimb lameness. In racehorses, bilateral lameness, such as in the carpi or metacarpophalangeal or metatarsophalangeal joints, is common. The clinician should carefully examine the contralateral limb. Predictable compensatory or secondary lameness often exists in the ipsilateral or contralateral forelimb when primary lameness is present in the hindlimb, or vice versa. In a Thoroughbred (TB) racehorse with left forelimb lameness, compensatory problems in the right forelimb and left hindlimb are not uncommon, because these limbs presumably are succumbing to excessive loads while protecting the primary source of pain. In a trotter, diagonal lameness often occurs (primary lameness in the left hindlimb and compensatory lameness in the right forelimb), whereas in pacers, ipsilateral lameness is

most common (primary right forelimb and compensatory right hindlimb). When several limbs are involved, identification of the primary or major source of pain is important. If forelimb and hindlimb lameness exist simultaneously, diagnostic analgesic techniques should begin in the hindlimb (see Chapter 10). A common secondary lameness abnormality, proximal suspensory desmitis, can develop in the compensating forelimb or hindlimb.

Coexistent lameness can make assigning primary or baseline lameness to a particular limb during lameness examination difficult (see Chapter 7). Bilaterally symmetrical pain may cause a short, choppy gait, but primary or baseline lameness often cannot be seen when the horse is examined in a straight line in hand. Often, horses with coexistent lameness must be circled, lunged, or ridden for primary or baseline lameness to be observed. The lameness diagnostician may have to arbitrarily assign lameness to a limb and begin diagnostic analgesia in this manner. Often, once the primary source of pain has been identified, horses show pronounced lameness of much greater magnitude than expected in another limb, vivid clinical evidence that coexistent lameness exists.

LAMENESS DISTRIBUTION

Among all types of horses, forelimb lameness is more common than hindlimb lameness. A horse's center of gravity or balance, while dictated to a certain extent by conformation (see Chapter 4), is not located in the center

of the horse but is closer to the forelimbs than the hindlimbs. Thus the forelimb/hindlimb (F/H) weight (load) distribution ratio is approximately 60%:40% (Figure 2-1). Higher loads are expected on the individual forelimbs (30% each), predisposing the horse to greater injury.

At certain times during the stride cycle of gaits such as the canter (three-beat gait) and gallop (four-beat gait), a single forelimb is weight bearing, which predisposes the limb to injury. The weight of a rider may shift F/H load distribution to 70%:30% (Figure 2-2). Two-beat gaits, such as the pace and trot, allow more equal load sharing between forelimbs and hindlimbs because a forelimb and hindlimb (ideally, if the gait is balanced perfectly) hit the ground simultaneously. In pacers and trotters the proportion of forelimb lameness is less than in the TB racehorse. The added load of pulling a sulky, cart, or any heavy load increases the likelihood of hindlimb lameness in Standardbreds (STBs), other harness breeds, and draft horses (Figure 2-3). The F/H distribution of lameness in STB racehorses is 55%:45%. Sporting activities such as dressage and jumping also may shift lameness distribution to the hindlimbs because collection (working off the hindlimbs) and propulsion needed by horses to perform these activities may predispose to hindlimb lameness. The tendency of good moving dressage horses to show advanced diagonal placement in trot results in a single hindlimb bearing weight.

In the forelimb, up to 95% of lameness problems occur at the level of or distal to the carpus.⁴ The distal parts of the limb always should be excluded as a potential source

Fig. 2-1 • The center of balance (gravity) of the horse is located closer to the forelimbs, which accounts for the load distribution difference between the forelimbs and hindlimbs. Conformation, namely the angles of the shoulder and rump, and weight of the head and neck and gait can change this load distribution.

Fig. 2-2 • Gaits such as the canter and gallop (depicted) and the added weight of a rider, as shown here in a Thoroughbred racehorse, increase load on the forelimbs by shifting the center of balance, thus increasing the likelihood of forelimb lameness.

of lameness before the upper limb is addressed, although many owners believe otherwise and may try to mislead an inexperienced practitioner. The foot should be suspected first. Pain in the foot is one of the most common causes of forelimb lameness in all types of horses, and in draft breed horses, the foot is also the most common site of pain in the hindlimb.

Hindlimb Lameness

Hindlimb lameness should not be underplayed, although its recognition is more difficult. In the forelimb lameness-prone TB racehorse, many hindlimb lameness problems are overlooked. However, a rider or jockey often may suspect a hindlimb problem when the lameness actually exists in the forelimb.

A practitioner should consider carefully the distribution of sites of hindlimb lameness. Historically, the hock has been regarded as the major source of problems, and although it is an important source of hindlimb lameness, other sites also are important. For instance, in both the TB and STB racehorse the metatarsophalangeal joint is a major source of lameness that historically has been overlooked.^{5,6} Maladaptive or nonadaptive bone remodeling of the distal aspect of the third metatarsal bone cannot be seen

radiologically in early stages and requires careful diagnostic analgesic techniques to achieve localization. Scintigraphic examination is mandatory for definitive diagnosis.⁷ Lameness of the metatarsophalangeal joint in STBs is almost as common as that of the hock, but without careful examination and the use of diagnostic analgesia, hock lameness is suspected in many such horses and they are treated for it. In sports horses proximal suspensory desmitis is now recognized as a more important cause of lameness than hock pain. The combined use of diagnostic analgesia, ultrasonography, and scintigraphy has increased clinical knowledge of the broad spectrum of lameness conditions in the hindlimbs.

In the draft horse, lameness in the hindlimb most commonly develops in the foot. Lameness in this area reflects the work performed by these horses, and innate characteristics of the draft horse foot, which predispose the foot to conditions such as laminitis. In jumping and dressage horses, problems in the fetlock region such as osteoarthritis and tenosynovitis are common and reflect the stress imposed by these disciplines. Although owners, trainers, and veterinarians often suspect an upper hindlimb lameness, gait characteristics of lower limb lameness problems often are similar. Only use of diagnostic analgesia allows an accurate diagnosis.

Fig. 2-3 • In a Standardbred racehorse (pacer depicted), the hindlimbs share added load compared with a Thoroughbred racehorse because of a caudal shift in the center of balance. The type of harness with the overcheck bit, the added weight of the sulky and driver, and the necessity of pulling a load increase the likelihood of hindlimb lameness in this breed.

RELATIONSHIP OF LAMENESS AND CONFORMATION

Conformation of the distal extremities, and to a lesser extent the overall body, plays a major role in the development of forelimb and hindlimb lameness (see Chapter 4). When a practitioner examines a weanling or yearling with poor conformation, predicting the time and the exact way the lameness will occur may be difficult, but many well-recognized conformational faults can lead directly to lameness problems. Conformational faults of the carpus, such as carpus varus or valgus, back-at-the-knee, and offset knees, can be important factors in carpal and lower forelimb lameness. In the hindlimbs, excessively straight hindlimbs (“straight behind”) and sickle-hocked and in-at-the-hock conformation can lead directly to predictable lameness conditions. Although exceptions do exist, in the case of poor conformation, predictable lameness conditions consistently develop in poorly conformed horses. Evaluation of conformation is therefore an essential part of a lameness examination.

POOR PERFORMANCE

Convincing trainers and owners may be difficult, but the leading cause of poor performance in racehorses is lameness, and lameness is the most prevalent health problem among all horses.⁸⁻¹¹ In one study, 50% of North American

operations with three or more horses had one or more lame horses, and 5% of the horses could be expected to be lame.¹⁰ In another study, 74% of racehorses evaluated for poor racing performance had substantial musculoskeletal abnormalities contributing to poor performance. Lameness examination was emphasized as a most important aspect of comprehensive performance evaluation.^{12,13} Others have emphasized the importance of lameness in epidemiological studies evaluating wastage in TB racehorses.^{14,15} Recently, lameness was once again found to be the most important condition causing missed training days in TB racehorses training in the United Kingdom.¹⁶ Two-year-olds missed training days significantly more than 3-year-olds, and stress fractures were the most important cause of lameness.¹⁶ Disappointingly, there has been little change in the importance of lameness and missed training days in the United Kingdom over a 20-year period.¹⁶ The same is likely true among all sports horses, particularly those competing at upper levels, although comprehensive studies have not been performed. Obvious lameness need not be demonstrated for performance to be compromised in horses, especially those competing at high speeds or upper levels. The possibility of achieving maximal performance in horses with substantial lameness is a common misconception. I have examined numerous top-level STB and TB racehorses in which easily recognized lameness is seen when the horses are trotted in hand on a hard surface. Notwithstanding the ignorance of many in the horse industry, the ability

of many horses with obvious lameness to compete is a tribute to their mental and physical toughness. For example, bilateral forelimb or hindlimb lameness is common in racehorses but in some instances goes unrecognized if the condition is of similar severity in both limbs. Unilateral lameness of this magnitude would be recognized easily, but because the lameness is bilateral, horses still race, albeit at a lower level. Bilateral third carpal slab fractures and sagittal fractures of the proximal phalanx have been diagnosed in horses examined for poor racing performance but, if seen unilaterally, would have caused pronounced lameness. Part of the art of the lameness examination is separating those horses capable of performing with moderate pain at a high level from those that cannot do so.

GAIT DEFICITS NOT CAUSED BY LAMENESS

Gait abnormalities can exist with or without the presence of clinically apparent lameness. Deficits such as stringhalt, mild intermittent upward fixation of the patella, and shivers (see Chapter 48) can be present without obvious lameness and may complicate diagnosis of a completely different primary source of pain causing lameness. Horses with neurological disease may have gait deficits that are considered the result of painful lameness conditions (see Chapter 11). Horses with lower motor neuron diseases, such as equine protozoal myelitis, may have lameness associated with muscle atrophy or unexplained low-grade lameness associated with the disease. Concomitant lameness conditions can and do occur in these horses. Recurrent exertional rhabdomyolysis can cause stiffness and in some instances lameness, or it can cause poor racing performance, all of which can be misinterpreted as lameness (see Chapter 83).

UNEXPLAINED LAMENESS

A diagnosis is made for most, but not all, lame horses through careful clinical examination and ancillary imaging modalities. Even with advanced imaging techniques, a solution is not always found (see Chapter 12), but it is hoped that future innovations in clinical examination and imaging will result in the continued expansion of the science of lameness diagnosis.

COMPONENTS OF THE LAMENESS EXAMINATION AND LAMENESS STRATEGY

Lameness Examination

Lameness examinations should be performed in an orderly, step-by-step way, but many factors may change or abbreviate the examination (Box 2-1). Owner financial constraints may not allow performance of certain diagnostic tests and may curtail the time necessary to complete the entire examination. Drug testing of competing racehorses or show horses may limit a practitioner's ability to perform diagnostic analgesic techniques and restrict management options. Clients do not always understand the need for diagnostic analgesia. Education about the value of this technique, and the difficulties of interpretation of the results of diagnostic imaging without it, is vital.

Abbreviated lameness examinations often are performed in horses that exhibit severe lameness compatible with a

BOX 2-1

Components of the Lameness Examination

- History—anamnesis
- Examination from a distance—conformation, symmetry, posture
- Palpation
 - Hoof tester examination
- Physical examination—other ancillary testing
- Movement
 - Baseline
 - Additional movement
- Selected examinations—manipulation, flexion, direct pressure, wedge
- Diagnostic analgesia
- Imaging
- Diagnosis
 - Certain, presumptive, open
- Management
- Follow-up examination

fracture. Typical or obvious clinical signs may accompany severe lameness, and in many instances prolonged or extensive lameness examination is contraindicated. If incomplete fractures are suspected, diagnostic analgesic techniques may be dangerous and should be performed only in certain situations. A clinician may proceed directly to conventional or advanced imaging techniques before completing the initial steps of a conventional lameness examination.

Many other factors affect the ability to complete a comprehensive evaluation. Time constraints (usually of the veterinarian) often are cited, although shortcuts, if taken, usually create future problems. Omission of a diagnostic block or failure to perform detailed palpation often leads to misdiagnosis. Omission of a brief physical examination, including assessment of the horse's temperature, can lead to embarrassing situations.

The footing available on which to complete the lameness examination can be problematic. A dry, flat, hard surface or space for lunging or riding may be unavailable. The horse's temperament may preclude adequate movement and often limits the practitioner's ability to perform diagnostic analgesia. Many ill-tempered horses are referred for advanced imaging techniques, such as scintigraphic examination, because diagnostic analgesic techniques are dangerous to the veterinarian and handler.

Lameness Etiquette

Owners frequently request an opinion from more than one veterinarian. Therefore professional, ethical conduct is important, with practitioner acknowledgment that horses can appear very different every day and that response to diagnostic analgesia is not always consistent. For example, differences of opinion concerning radiological interpretation can exist. A good working relationship with the client or agent is essential but should extend also to the farrier and any paraprofessionals involved in the management of the horse, even when opinions differ.

Prognosis Assessment

Assessment of prognosis for performance is important, but because few published data relating to many sports disciplines are available, clinicians often must rely on

personal experience based on an understanding of the sport. Owners and trainers should consider prognosis carefully when making decisions to pursue therapeutic options, particularly when a long layoff period is required. I prefer to define prognosis as the “chance the horse will return to its previous level of competition.” However, this may not be a fair or reasonable definition.

Retrospective studies can be used to evaluate prognosis after surgical or conservative management for various conditions in racehorses. Objective data such as numbers of race starts, race times, earnings per start, and time from treatment to first race start can be assessed. Earnings per start is an important criterion because it establishes racing class or level of competition. However, in most retrospective studies, earnings per start decrease after treatment. The question is whether practitioners can accurately state that the horse will drop in class after treatment and whether this drop in class is the result of the injury, treatment, or aging of the horse an additional year before returning to racing. Use of this information is not easy.

Most owners and trainers have a different view of prognosis than the veterinarian. In considering the prognosis for a horse undergoing arthroscopic surgical removal of a small osteochondral fracture of the carpus, most owners emphasize the surgery rather than the original injury. Clinicians must explain thoroughly the magnitude of the injury and related damage and discuss prognosis, using terminology that clearly indicates that the extent of injury is the factor that determines prognosis.

Expecting a racehorse to return to its previous racing class may be an unrealistic expectation or at least a very strict definition for success. In a retrospective study of postoperative racing performance of STBs treated for carpal chip fractures, 74% of horses made at least one race start after surgery.¹⁷ Median earnings per start significantly decreased, but the median race mark (best winning time)

also significantly decreased, indicating that horses made less money but raced faster after surgery.¹⁷ These results must be compared with a normal population of STBs as the horses age, without considering injury, because STB racing performance is not standard over time.¹⁸ Average earnings per start is highest in 2-year-old horses and decreases exponentially until retirement.¹⁸ A population of horses undergoing any long-term layoff that requires recommencement of racing the following year can be expected naturally (unrelated to the original injury) to have lower earnings per start, regardless of whether an injury occurred or treatment was given. Therefore retrospective studies may underestimate prognosis associated with injuries and management choices.

Success criteria and outcome assessment must be standardized to compare treatment results and to define prognosis. The current standard for racehorses is comparison of performance for five starts before and after injury and treatment. This criterion is strict; a practitioner first may prefer to predict the chance of the horse returning to racing and then assess the chance that the horse will perform at or near its previous level.

Other statistical methods have been used to evaluate racing performance in TBs using a regression model accounting for variables such as track surface, race distance, and age.¹⁹⁻²¹ To date, this performance analysis has been restricted to evaluation of horses after upper respiratory tract surgery but probably will be applied to horses with musculoskeletal injuries.

When comparing published information regarding management of various types of lameness, the clinician should be clear about criteria for inclusion of cases and be sure to compare “apples to apples.” For instance, comparing results of management of horses with chronic, recurrent hindlimb suspensory desmitis to those with acute forelimb suspensory desmitis is unfair.

Chapter 3

Anamnesis (History)

Mike W. Ross

The importance of a detailed clinical history, the anamnesis, cannot be overemphasized. Information is divided into two categories: basic facts necessary for every horse, and additional information from questions tailored to the specific horse. The veterinarian must understand the breed, use, and level of competition of each horse, because prognosis varies greatly among different types of sports horses. Firsthand experience of the particular type of sports horse being examined is useful but is not essential. Clinicians must understand the language associated with the particular sporting event, and this may be a challenge. For some sporting events, understanding the clinical history and having the ability to ask the right questions are like

speaking a different language. A veterinarian unfamiliar with the sporting activity should briefly review the type of activities performed and the array of potential lameness problems encountered with them (see Chapters 106 to 129). In some instances the veterinarian may lose credibility when talking to trainers or riders, particularly those involved in upper-level competition, if they perceive unfamiliarity.

The veterinarian must understand the difference between subjective and objective information in the clinical history. Objective information is gained from the horse, and subjective information is perceived by the rider or owner. Knowledge about a horse's performance such as “the horse is bearing out,” “the horse is on the right line,” “the horse is lugging in,” “the horse has just started to refuse fences,” or “the horse no longer takes the right lead” is valuable objective information. Common examples of information perceived by the owner or rider include “the horse feels off behind,” “the horse is stiff behind,” or “the horse is lame behind” and it “feels up high.” Such information generally is useful and indicates a change in the horse's gait, but only an experienced rider or trainer

can discriminate accurately between forelimb and hindlimb lameness at any gait. Erroneous information obtained from the rider can complicate communication during lameness examination, particularly if the individual is strong-willed and seemingly authoritative; this situation occurs if riders or trainers insist they are correct and the veterinarian disagrees. In my experience, many horses considered to have hindlimb lameness by a rider actually are lame in front, but convincing a disbelieving trainer is difficult. Similarly, lameness perceived as “up high” (in the upper hindlimb, pelvis, or back) in most horses originates from the lower part of the hindlimb. The veterinarian must understand that everyone is trying to resolve the problem, but sometimes diplomacy is needed for successful communication. The veterinarian must be forthright and objective to determine the current source of lameness, even if the determination contradicts well-intentioned but strong-willed trainers.

Clinical history is important but should not override clinical findings. In racehorses that perform at high speed, physical examination generally supports the finding that a horse bears away from the source of pain. During counter-clockwise racing or training and with left forelimb lameness, a Thoroughbred (TB) will lug out (away from the inside of the track) and a Standardbred (STB) will be on the “left line” (bearing out; the driver must pull harder on the left line). Some horses, however, especially STBs with medial right forelimb pain, bear out particularly in the turns, presumably because the source of pain is medial or on the compression side of the limb.

The veterinarian must seek out as much information as possible, particularly if the problem is complex or not readily apparent. Videotapes are useful, particularly if the gait deficit, behavioral problem, or any other circumstances necessary to elicit the suspected lameness cannot be duplicated during the examination. Paraprofessionals working with the horse provide useful information, but not everyone may agree about the source of the problem, and in some instances diplomacy is key to negotiating among concerned individuals.

CLINICAL HISTORY: BASIC INFORMATION

Signalment

Age

The age, sex, breed, and use of the horse are basic vital facts (Box 3-1). Flexural deformities, physitis, other manifestations of osteochondrosis, and angular limb deformities are age-related problems. Infectious arthritis (hematological origin), lateral luxation of the patella, and rupture of the common digital extensor tendon are conditions usually unique to foals. Emphasis on training skeletally immature, 2- and 3-year-old racehorses causes predictable soft tissue and bone changes, often resulting in stress-related cortical or subchondral bone injury. Liataud observed more than 100 years ago: “When an undeveloped colt, whose stamina is not yet established and constitution not yet confirmed, with tendons and ligaments relatively tender and weak, and bones scarcely out of the gristle, is unwisely condemned to hard labor, it is irrational to expect any other results than lesions of one or another portion of the abused apparatus of locomotion. They will be fortunate if they

BOX 3-2

Summary of Lameness Conditions of the Geriatric Horse

Chronic, progressive osteoarthritis
 Proximal and distal interphalangeal joints
 Metacarpophalangeal joint
 Carpometacarpal joint*
 Coxofemoral joint*
 Femorotibial joints
 Tarsus
 Progressive osteoarthritis—previous injury (usually retired racehorses)
 Navicular disease
 Unexplained, severe soft tissue injuries*
 Superficial digital flexor tendonitis
 Flexural deformity
 Suspensory desmitis
 Fractures during recovery from general anesthesia

*Some of these conditions are unique to the older horse and often are unexplainable.

escape a fate still worse, and become sufferers from nothing worse than mere lameness.”¹ This statement aptly summarizes the situation then and now. The high value of races for 2- and 3-year-olds results in high-intensity training for early 2-year-olds, which may result in injury such as maladaptive or nonadaptive remodeling of the third carpal bone (C3), precluding racing at a young age.

Some problems are unique to older horses (Box 3-2). Overall, osteoarthritis (OA) and other degenerative

Fig. 3-1 • An aged Thoroughbred broodmare with severe forelimb deformity caused by primary severe osteoarthritis of the right metacarpophalangeal joint and secondary or compensatory (chronic overload) carpus varus in the left forelimb.

Fig. 3-2 • Dorsopalmar digital radiographic image of the right carpus in a 13-year-old Arabian mare with pronounced lameness as a result of severe, progressive osteoarthritis of the carpometacarpal and middle carpal joints (medial is to the right). There is substantial varus limb deformity present. Comfort improved after partial carpal arthrodesis. (Courtesy Dr. Dean Richardson.)

conditions such as navicular disease are most common but certainly are not unique to the geriatric horse. Some horses have a remarkably early onset of navicular disease or OA despite little physical work, suggesting a genetic predisposition to the condition. These problems worsen with advancing age, particularly if several limbs are involved. In former racehorses, progressive OA is of particular concern; this condition most commonly affects the carpal and metacarpophalangeal joints (Figure 3-1). Occasionally in older horses, severe, progressive OA of the carpometacarpal joint occurs without any history of carpal lameness (Figure 3-2). In some horses, angular deformities (the most common is carpus varus) develop at the carpometacarpal joint. Inexplicably severe OA of the carpometacarpal and middle carpal joints is most commonly seen in Arabian horses (see Chapter 38). Primary OA of this joint is rare in young horses, even in racehorses with middle carpal joint abnormalities, unless C3 slab fracture or infectious arthritis occurs. OA of the coxofemoral joint is rare in horses with the exception of young horses with osteochondrosis, but it does occur in older horses.

An unusual group of soft tissue injuries of unknown origin occurs in older horses. Superficial digital flexor tendonitis and suspensory desmitis generally are considered overuse injuries and usually occur in upper-level performance horses or racehorses. However, severe tendonitis and desmitis do occur, often suddenly and without provocation, in older (teenage) horses. Horses usually are turned out at pasture when initial lameness is observed. In some horses, superficial digital flexor tendonitis is severe and progressive, later leading to flexural deformity because of adhesions. Suspensory desmitis may be unilateral or

bilateral, may involve the forelimbs or hindlimbs but is more common in the hindlimbs, and is most common in the older broodmares. The name *degenerative suspensory (ligament) desmitis* (DSD) was given to a syndrome, often seen in older horses and most common in Peruvian Pasos, in which severe, often bilateral suspensory desmitis occurred²⁻⁴ (see Chapter 72). In a recent study horses other than Peruvian Pasos were affected, and an alternative name—*equine systemic proteoglycan accumulation*—was proposed, because abnormal accumulation of proteoglycans in many connective tissues was found.⁴ However this has recently been disputed⁵; the suspensory ligaments (SLs) and other tissues from affected Peruvian Pasos and unaffected STB and Quarter Horses were examined using Safranin-O staining for detection of proteoglycan. Proteoglycan deposition was not unique to the affected Peruvian Pasos, being present in the nuchal ligament, heart, muscle, and other tissues, with similar or greater amounts in the control horses. However greater amounts were detected in the SLs of affected horses compared with control horses. It was concluded that cartilage metaplasia and associated proteoglycan deposition in affected SLs was the response to injury rather than the cause. Further work is needed to define this important disease.

Older horses, particularly older broodmares, are at greater risk than younger horses to fracture long bones during recovery from general anesthesia.⁶ From 1988 to 1994, 9 of 14 horses with catastrophic fractures or dislocations that developed during recovery from general anesthesia were older than 10 years of age.

Age prominently affects prognosis. A common premise in considering lameness in foals is that young horses have time to outgrow the problem. Maturation will aid in angular limb deformities, some forms of osteochondrosis, and distal phalanx and diaphyseal fractures. However, fractures of important physes such as the proximal tibia may result in progressive angular deformities or disparity in limb length, limiting future prognosis. Early surgical management of flexural deformity of the distal interphalangeal (DIP) joint before 6 to 8 months of age optimizes future soundness and the possibilities for normal hoof conformation. In one study the reported success rate was 80%.⁷ If surgical management is undertaken later in life or when deformity is severe, the prognosis decreases substantially. The prognosis for survival of foals treated for infectious arthritis is reasonable, but only 31% of TB foals and 36% of STB foals started one or more races, indicating that the prognosis for future racing performance is poor, because articular healing even in young foals is not possible.⁸

In middle-aged (12 to 18 years of age), upper-level performance horses, prognosis is difficult to assess, particularly in horses with several problems. Level of competition rather than age may be the most important factor, and often performance level declines.

Sex

Most lameness conditions affect stallions, geldings, and mares with similar frequency. Sex-specific conditions are unusual but do exist. The most important consideration, however, regarding the horse's sex is future breeding potential or lack thereof in the case of geldings. In many types of horses, and specifically in racehorses, decisions about future performance or racing potential often are important when management options and financial aspects are considered. This factor is particularly important when life-or-death decisions must be made after catastrophic injury (see Chapters 13 and 104). Frank discussions about the prognosis for return to the current sporting activity or level of performance often are necessary, and the clinician should consider reproductive capability of the horse. Owners are more likely to refrain from racing females and elect treatment for geldings and, in some instances, stallions. Future stallion prospects usually must prove race or performance success, thereby putting pressure on trainers to continue horses in training or racing.

Behavioral abnormalities associated with the estrous cycle in fillies or mares are well recognized and may cause performance problems confused or misinterpreted as lameness (refusing fences, going off stride, striking) (see Chapter 12). An ill-defined behavioral problem in middle-aged nonracehorse mares could explain sudden performance problems often associated with or misinterpreted as lameness.⁹ Recurrent exertional rhabdomyolysis (RER) is more common in female TB racehorses¹⁰ and event horses.¹¹ An association between sex and RER in STBs may exist and RER may be more common in fillies administered anabolic steroids.

Obscure or unexplained hindlimb lameness has been attributed, rightly or wrongly, to retained testicles. The origin of lameness in these horses is difficult to prove without removing the retained testicle, and anecdotal reports suggest that hindlimb lameness has resolved after

castration in some horses. The origin of pain in an abdominal cryptorchid is difficult to explain and questionable. The source of pain may be easier to understand in a horse with a testicle located within the inguinal canal. Activity of the external and internal abdominal oblique muscles and tension on the spermatic cord are possible explanations.

Breed and Use

Most lameness conditions affect all breeds of horses. Although breed has considerable influence on sporting activity, sporting activity or use primarily has the greatest impact on lameness distribution (see Chapters 106 through 129).

Current Lameness

Determination of the Problem

Accurate information is necessary to determine precisely the horse's current problem. Obtaining reliable information may be difficult if the horse has been purchased recently, if the horse has been claimed or changed trainers, or if you are giving a second opinion and have no past history with the horse. Additional objective information may be necessary to assess the effect of lameness on the horse's performance. Evaluation of the horse's race record may indicate when the problem began and if it is ongoing or new. The groom, rider (if not the owner), assistant trainer, blacksmith, and other paraprofessionals may have other pertinent information. Horses with poor performance usually are lame, although respiratory problems, rhabdomyolysis, shoeing, tack or equipment, and other medical problems can contribute.

The horse's past history is important in determining the cause of the current problem, particularly in racehorses training or racing with existing low-grade OA that develop new overload injury to supporting limbs (secondary or compensatory lameness). Existing problems such as OA worsen insidiously but may reach critical levels, causing sudden, severe unexpected lameness. OA of the metacarpophalangeal joint may exist for months in racehorses without causing obvious lameness, although in many horses joint effusion ultimately leads to treatment ("maintenance injections"). The horse suddenly may be much lamer after racing or training, and the trainer may assume the cause is different. Because intraarticular analgesia may only partially relieve lameness, persuading the trainer that the problem is still the fetlock may be difficult. Horses can endure extensive cartilage damage in any joint for many months, but at some point they reach a threshold level beyond which they cannot tolerate the pain.

History of Trauma

Many lameness problems develop during or shortly after a traumatic incident, but unfortunately many owners presume trauma played a role even when no one witnessed an alleged incident. A common but often erroneous assumption when examining a lame foal is that the dam stepped on it, but usually infection is the cause. Clinical signs of osteochondritis dissecans of the shoulder or stifle often are expressed after a traumatic incident, and yet most lame weanlings or yearlings are assumed to be lame because of trauma, not a developmental problem. Some lameness

problems appear after specific forms of trauma. Palmar carpal fractures occur most commonly in jumpers, but horses recovering from general anesthesia are at risk for this injury. Horses may be only mildly lame immediately after recovery, and the extent of injury is often not discovered until nonsteroidal antiinflammatory medication is discontinued, sometimes 7 to 10 days after the surgical procedure. A common history of horses with subluxation of the scapulohumeral joint (often called *Sweeny* or *suprascapular nerve injury*) is sudden profound lameness after being outside in a thunderstorm. Injury likely occurs when a horse runs into a solid object such as a tree, fence post, or building.

Duration

The veterinarian must understand the duration of the current lameness problem and determine whether a preexisting chronic, low-grade lameness exists and a sudden exacerbation of this problem has occurred, or a completely unrelated new problem has developed.

Worsening of Condition

The veterinarian must establish if the horse's current problem is worsening or improving, under which conditions or circumstances the lameness deteriorates or improves, and if the horse responds to treatment such as shoeing or management changes. Most lameness problems worsen with time, particularly if training or performance continues despite owner or trainer recognition. Racehorses with stress-related bone injury often are noticeably lame after work but become sound relatively quickly, within 1 to 3 days. A minimal number of other clinical signs are present, particularly because the most commonly affected bones (tibia, humerus) are difficult to palpate and buried by soft tissue. This cycle of lame-sound-work-lame is an important part of the history.

Improvement of lameness with rest is important from historical and therapeutic perspectives. Lameness in most horses with severe articular damage, usually from severe OA, does not improve substantially with rest. Severe OA most commonly appears in the fetlock, femorotibial, and tarsocrural joints. Horses with fractures or mild to moderate soft tissue injuries generally improve with rest.

Warming into Lameness

Warming into lameness means the horse's lameness worsens during the exercise period. *Warming out of lameness* means the lameness improves. This concept is important. Lameness associated with stress or incomplete fractures, soft tissue injuries (tendonitis and suspensory desmitis), splints, curb, and foot soreness worsens with exercise. In racehorses a worsening lameness appears as progressive bearing in or out during training or racing. In riding horses, this may be progressive stumbling, problems taking leads, progressive asymmetry in diagonals, or refusing to jump later fences. Horses with OA may be stiff and obviously lame at a walk, but lameness may improve with work. In western performance horses, OA of the proximal and distal interphalangeal joints and in some horses navicular syndrome cause lameness with this characteristic. The most dramatic example is distal hock joint pain, particularly in racehorses. Horses may be noticeably lame at a walk and trot, warm out of the lameness to the point of racing

successfully, and then show pronounced lameness after a race.

One frequent statement at the racetrack is that the horse throws the lameness away at speed. This decrease occurs with some lameness conditions, such as distal hock joint pain, but two other factors are important. A horse may be able to race with lameness but not be able to perform at peak, particularly if lameness is bilateral. Horses often can race with bilateral conditions and show minimal signs of lameness, but performance is reduced. Lameness at the gallop may be impossible to perceive, and even at the fast trot or pace, most persons have difficulty seeing lameness. The same limitation occurs in observing a dressage or jumping horse at the canter. The veterinarian may gain some information by observing that a horse is reluctant to take either the left or right lead, but lameness is difficult if not impossible to detect at the canter. Unless slow-motion video analysis is available, the horse appears to be able to "throw lameness away," but lameness is present but difficult to see. In this situation, horses do not warm out of lameness but simply cope with the pain while racing. Horses in this situation are at risk for developing compensatory problems.

Older horses with OA may have difficulty in getting up and later warm out of the lameness. Horses of any age with pelvic fractures or severe lameness may have difficulty in rising.

Recent Management Changes

Many lameness conditions start after a change in management. Changes in shoeing, training or performance intensity, surface, housing, and diet or other medical issues can have a profound effect on the musculoskeletal system. Changes in ownership often dictate changes in exercise intensity and certainly in owner expectations. The veterinarian must be careful in questioning and responding to questions if a horse has been purchased recently, especially if a colleague performed a prepurchase examination. Clinicians should avoid implying that a condition may have been preexisting or missed.

Shoeing

The veterinarian should determine when the horse was last shod and whether the shoeing strategy was changed. Nail bind often causes acute progressive lameness related temporally to shoe application. Abscesses that result from a "close nail" may take several days to cause lameness.

Foot balance is critical and, in some horses, changing foot angles results in lameness. A substantial increase or decrease in heel angle in a horse with chronic laminitis may exacerbate lameness. In horses with palmar foot pain, raising the heel angle may produce an obvious improvement in clinical signs briefly, whereas in horses with subchondral pain of the distal phalanx, raising the heel may worsen clinical signs. In racehorses with "sore feet" resulting from soft tissue and bone pain, changing shoes may result in improvement, related in part to temporary reduction in weight bearing in the painful area of the foot.

Temporary lameness often occurs in horses with recently trimmed but unshod hooves, particularly if the horses' hooves are trimmed aggressively or the ground is unusually hard for that time of year. The veterinarian must

remember that a horse with recently trimmed hooves often shows bilateral forelimb lameness when trotted on flat or uneven hard surfaces, regardless of the primary cause of the current lameness. The horse should be reassessed on a soft surface.

Attempts to make both front feet symmetrical may create substantial lameness immediately after trimming. Horses may cope well with different size and shaped front feet, but when radical trimming is performed, they may develop severe lameness.

The veterinarian must determine whether any recent or past changes in shoeing either improved or worsened lameness. Lameness in a STB trotter with foot pain may be improved by changing from conventional shoes, such as half-round or flat steel shoes in the front to a “flip-flop” shoe.

The farrier often first notices a common problem that a horse is reluctant to pick up the hindlimbs. In some horses this problem is purely behavioral, whereas in others it is a real sign of pain. This history most often is associated with conditions such as OA of one or more joints but also may be a sign of pelvic or sacroiliac pain. In Warmbloods, draft breeds, and draft-cross horses, reluctance to pick up a hindlimb may be an early sign of shivers.

Training or Performance Intensity

Lameness that worsens in response to recent increase in training intensity may be related to stress-related subchondral or cortical bone injury. Stress fractures, bucked shins, or maladaptive or nonadaptive stress-related injuries of subchondral bone occur typically during defined periods of training and often after brief periods of rest. When horses in active race training are given time off, even brief periods such as 7 to 21 days, bone undergoes detraining, leaving it subject to stress-related injury. If training resumes at the prerest level or is accelerated, stress fractures or bucked shins often develop. In 3-year-old TBs, stress fractures of the humerus often occur within 4 to 8 weeks after returning to training. Bucked shins often develop in 2-year-old TB racehorses after a brief rest period for an unrelated medical condition.

Surface

Most lameness conditions worsen if the horse performs on a harder surface. In show horses such as the Arabian or half-Arabian breeds, foot lameness often results when horses are warmed up or shown on harder surfaces. An association exists between fracture development and hard racing surfaces. A dramatic change in any racing surface may lead to unexpected episodic lameness in racehorses. On breeding farms, anecdotal evidence suggests drought conditions causing harder than normal pastures lead to a higher prevalence of osteochondrosis or distal phalanx fractures.

Lameness that is most pronounced on hard surfaces is often seen with conditions of the foot. Lameness that worsens on softer surfaces, however, may be associated with soft tissue injuries such as proximal suspensory desmitis. Uneven surfaces may exacerbate lameness and other gait abnormalities. Horses prone to stumbling on uneven surfaces may have palmar foot pain, proximal suspensory desmitis, or neurological disease. Horses with bilateral lameness may be lame in one leg going in a particular

direction on a banked surface (such as a racetrack) and lame in the opposite leg going the other way. Bilateral lameness may be confused with other causes of poor performance because of inconsistencies in gait. Lameness may worsen or improve when a horse goes uphill or downhill.

Diet and Health

Changes in diet or dietary factors may lead to or exacerbate existing lameness conditions. Dietary factors, especially dietary excesses or deficiencies, are important in the many manifestations of developmental orthopedic disease (see Chapter 55). Sudden changes in diet, such as those associated with turning horses out on lush pastures or consumption of large quantities of grain (grain overload), may cause laminitis or exacerbate existing chronic laminitis. Overweight horses normally consuming a high-grain diet may be prone to laminitis or gastrointestinal tract disturbances that lead to laminitis.

Lameness may be associated with, or result from, other medical conditions. Obvious associations exist in foals; for example, conditions such as infectious arthritis and physitis are associated with umbilical, gastrointestinal, or respiratory tract infections. Immune-mediated synovitis also occurs in older foals with chronic infections (see Chapter 66). In adult horses, infectious arthritis generally develops after intraarticular injections or penetrating wounds, but may result from hematological spread of bacteria. Occasionally, horses develop distal extremity edema and lameness after vaccination, presumably caused by vasculitis or other immune-related mechanisms. Similar signs appear in horses with purpura hemorrhagica or viral illnesses such as equine viral arteritis.

Housing

Many lameness conditions develop while a horse is turned out, or as the result of turnout, often as the result of trauma such as kick wounds or fence-related injuries. Sudden changes in weather may excite horses, particularly those turned out at pasture. Minimizing problems with turnout requires the use of well-groomed and well-maintained pastures or paddocks with individual paddocks to reduce horse-to-horse interactions.

Dramatic housing changes have a substantial impact on the development of lameness. Shipping to and from sales, foaling, and weaning are associated with soft tissue injuries, puncture or kick wounds, and other injuries.

Current Medication Changes and Response

The veterinarian must establish if the horse currently is receiving medication or was administered medication recently and the response to treatment. Response to medication or a management change is important information in formulating a treatment plan. For example, recent improvement with rest and the administration of nonsteroidal antiinflammatory drugs indicates more of the same treatment may be reasonable. The veterinarian must establish dosages of medication because a horse may not respond to phenylbutazone because of underdosage.

Many owners and trainers do not understand that although intraarticular analgesia relieves lameness, intraarticular medication may not, thus causing doubt about the diagnosis. This characteristic commonly appears in horses

with subchondral bone pain and is useful in diagnosis. Horses with early OA and negative or equivocal radiological signs, or those with short, incomplete fractures, often do not respond to intraarticular medication. Negative radiological findings are a good sign because dramatic radiological evidence of subchondral lucency or fracture reduces the prognosis considerably. However, convincing the trainer of the validity of the diagnosis may be difficult.

The amount of rest is important. Many acquired conditions, such as OA, or degenerative conditions, such as navicular syndrome, take many months and usually years to develop. Therefore expectation that a horse will show marked improvement with a brief rest period is unreasonable. Lameness in many horses with severe OA may not improve substantially, even with prolonged rest. In horses with early OA in which pain occurs primarily in subchondral bone and for which radiological findings are negative or equivocal, rest or controlled exercise for 3 to 6 months may be necessary. The same regimen applies for horses with navicular syndrome, fractures, and many soft tissue injuries.

Quality of rest is equally important. Did the horse receive absolute box stall rest with handwalking, or was it

lunged or turned out in a paddock or field with other horses? Was a brief rest period followed by an attempt to ride or train the horse? Those associated with the horse often consider this type of intermittent rest *complete* rest, but many conditions remain chronically active. Without adequate rest, reinjury follows temporary improvement and early healing, highlighting that, in my opinion, *turnout is the antithesis of healing!*

Past Lameness History

Obtaining the horse's entire lameness history may not be necessary or possible, but the veterinarian should gather as much information as is practically available. Prognosis for many injuries is affected adversely by recurrence, and often management options differ in these situations. Recurrence may prompt more aggressive therapy, considerations for referral, or perhaps surgical evaluation if the problem involves a joint. If a reliable diagnosis was made previously, retreatment for the past problem may be a reasonable or preferred management approach, particularly between races or competitions. If a horse responded previously to intraarticular medication, reinjection may be reasonable. However, in many horses with progressive OA, results of

Fig. 3-3 • Initial (A) and 2-week follow-up (B) dorsopalmar radiographic image of the left third metacarpal bone in an 18-year-old Thoroughbred gelding. The initial image was obtained after the horse was found to have a small skin wound in the region but was sound. Acute, severe lameness developed 9 days after initial injury, and the follow-up radiograph shows a long oblique fracture of the third metacarpal bone. (Courtesy Dr. Janet Durso, 2001.)

Fig. 3-4 • Craniocaudal radiographic image of the left antebrachium of a 5-year-old Thoroughbred mare showing a displaced, long oblique fracture of the radius. This filly had sustained a small puncture wound to the lateral aspect of the antebrachium 5 days earlier but was sound. The mare was turned out and developed acute, severe lameness and was later euthanized.

additional therapy often are diminished. The veterinarian should not assume that the failed response to intraarticular medication means the problem lies elsewhere because medication does not affect subchondral bone pain in early or late OA.

Recent history is important. Small, innocuous-looking wounds over the third metacarpal bone or third metatarsal bone, radius, or tibia may be associated with bone trauma with delayed-onset severe lameness. Incomplete or spiral fractures may develop from small cortical defects (Figure 3-3). Catastrophic failure of long bones occurs even when initial radiographs show no or minimal cortical trauma. The radius appears to be at greatest risk (Figure 3-4).

New problems may and often do arise despite a long history of recurrent lameness. Comprehensive reevaluation is the best and safest approach to avoid delays in proper diagnosis and treatment.

FURTHER INFORMATION

Full understanding of a horse's use, type and level of sporting activity, and value, all of which help the veterinarian assess prognosis, requires specific information. If a horse previously was under the veterinary care of another individual in the same or a different practice, it is important to obtain accurate case records and view previous radiographs and other images.

Chapter 4

Conformation and Lameness

Mike W. Ross and C. Wayne McIlwraith

The idea of a good horse with poor legs is a misnomer; the legs are the essence of the horse, and every other part of the equine machine is of only subservient and tributary importance.

A. Liataud¹

The thought that the way a horse is conformed determines the way it moves is well accepted. The relationship of conformation, especially of the distal extremities, and lameness also is well recognized. "Conformation determines the shape, wear, flight of the foot, and distribution of weight."² Veterinarians often are asked to comment on conformation during lameness and prepurchase examinations, especially with regard to the suitability of the horse to perform the intended task. In some instances, as in the case of presale yearling evaluations, the veterinarian's opinion is paramount, and purchase is contingent on judgment of the yearling's potential to perform as a racehorse, given its conformation, or in some instances its conformational faults (see Chapter 99). "It is by a study of conformation that we assign to a horse the particular place and purpose to which he is best adapted as a living machine and estimate his capacity for work, and the highest success in this connection will be best attained by the judicious blending of practice with science."³ Evaluation of conformation and its influence on lameness is based largely on observation, experience, and pattern recognition. Recognizing desirable conformational traits in horses suited for a particular sporting activity and learning when to overlook a minor fault that has little clinical relevance are important.

RELEVANCE OF EVALUATION OF CONFORMATION

Conformation is one piece of the complex puzzle of a lame horse, although poor conformation does not necessarily condemn a horse to lameness: "faulty conformation is not an unsoundness ... it is a warning sign."² All lameness diagnosticians should evaluate conformation briefly at the beginning of each examination. The association of lameness and faulty conformation will be obvious. The clinician must evaluate the horse from afar, assessing the whole horse for balance, angles and lengths, and posture and symmetry. The clinician must remember that horses come in all shapes, sizes, and types, and therefore conformation varies accordingly, but certain conformational faults produce predictable lameness conditions and are undesirable. However, good conformation is not synonymous with success, and although horses of certain body types tend to have longer strides and are more athletic than others, intelligence, aggression, "will to win," and other intangible factors are important. It is our opinion that a well-bred horse from a successful family can endure faulty conformation much better than one with poor or mediocre breeding.

HEREDITARY ASPECTS OF CONFORMATION

Certain conformational faults appear to be highly heritable traits. Evaluation of broodmares and foals often reveals that the early conformational defects seen in a foal are present in the dam. The dam seems to contribute more to faulty conformation than does the sire, although the stallion also is important. This difference may be explained in part by the fact that fillies with faulty conformation may develop problems or be retired early and subsequently bred, whereas most stallions usually are proven performers with exceptional conformation. Conformational faults such as toed in and toed out commonly are passed down from generation to generation. Back-at-the-knee (calf-knee), offset (bench) knee, tied-in below the knee, sickle-hocked, and straight-behind conditions appear to be highly heritable. In a recent study abnormal sire phenotype (offset carpi and outward rotation) was associated with faulty

yearling carpal conformation.⁴ Heavier foals and yearlings were more likely to have faulty carpal conformation and inward rotation of the fetlock joints.⁴

Certain lameness conditions are common in horses with faulty conformation, but similar lameness conditions develop inexplicably in some breeding lines year after year in offspring with apparently acceptable conformation. Lameness of the carpus or tarsus appears to be most important. For example, in Standardbreds (STBs), siblings commonly develop similar lameness conditions, such as proximal suspensory avulsion injury, carpal osteochondral fragments, distal hock joint pain, or curb.

OBJECTIVE EVALUATION OF CONFORMATION: IS IT POSSIBLE?

An attempt to quantify conformation using a linear assessment trait evaluation system that allows the observer to assess where, given a particular trait, a single horse falls within a population of horses, was described in 1996.⁵ A population of 101 Irish Thoroughbred (TB) flat racehorses and 19 top stallions was used and 27 common conformational traits were evaluated, including various heights, lengths and angles, and distal extremity conformation. Of the 27 traits, six were significantly linked to age (withers' height and conformation, back length, neck size, carpal conformation, and hind pastern conformation), and five were linked to sex (head and neck shape; neck size at the poll, the larynx the withers, and the manubrium of the sternum; and forelimb hoof pastern axis). Most traits exhibited large phenotypic variation within the population, but 21 of 27 non-age-linked traits were judged suitable for possible inclusion in a linear assessment protocol.⁴ Researchers judged a high percentage of horses to be toed out, suggesting this trait may even be desirable.

More recent studies have used video-image analysis, but direct physical measurements may be more accurate than those obtained by analyzing videotapes or photographs.⁶ Potential errors in image analysis occur because of movement of skin markers over selected bony protuberances, a phenomenon more common in the upper limb and in motion studies.^{6,7} Skin marker location is critical for evaluation of joint angulation and movement during locomotion or conformation analysis. Instantaneous center (or axis) of rotation (ICR) is defined as the point with zero velocity during movement of that joint; accurate measurements of joint angulation require positioning markers at the ICR.⁸ Conventional positions of skin markers and ICR in most joints agree well, but use of traditional marker sites on the scapulohumeral and femorotibial joints results in overestimation and underestimation, respectively, of caudal joint angles.⁹ Although video-image analysis may be fraught with potential or in some instances real error, objectivity is a major advantage. Other advantages include the ability to replay images, reduction of observer fatigue, elimination of observations and measurements in real time, and permanent recording of the observation. Ideally, objective measurements would withstand statistical evaluation, distinguish between desirable and undesirable traits, and account for differences among different types of horses.⁶

A combination of direct measurement and photography was used to evaluate conformation of Swedish

Warmblood (WBL) and elite sports horses.^{10,11} Whereas most of the conformational defects were mild or moderate, 80% of WBL horses were toed out behind, suggesting this may be a normal finding in this breed as in the STB trotter. More than 50% of horses had bench knees and 5% were toed out in front, contrary to findings in STB trotters.^{10,12} Many of the elite horses were bucked kneed, whereas the riding school horses tended to have calf-knees. It was speculated that this occurred because elite horses were evaluated after competition, and muscle fatigue may have contributed to the tendency to be over at the knee. Sex had a significant influence on conformation; females were smaller and had longer bodies and smaller forearms and metacarpal regions. There were interesting findings regarding hock angle. A sickle hock is defined as a hock angle of 53 degrees or less; a large hock angle is referred to as *straight behind*. Sickle-hocked conformation was nearly absent in elite horses, and it was hypothesized that sickle-hocked conformation either predisposed a horse to lameness or impaired a horse's ability to achieve upper levels of competition.¹⁰ A positive relationship between larger hock angles and soundness in STB trotters also exists.¹³ All results must be viewed in moderation, because it is our clinical impression that horses with excessively large hock angles (straight behind) are substantially predisposed to suspensory desmitis. In forelimbs of WBL show jumpers and the forelimbs and hindlimbs of STB trotters, smaller fetlock joint angles (less upright) were desirable.^{10,13}

Radiology was used to assess the degree of hyperextension of the carpus to study the potential effect of back-at-the-knee (calf-knee) conformation on the subsequent development of carpal chip fractures.¹⁴ Lateromedial radiographic images of 21 horses with carpal chip fractures and of 10 normal horses were obtained, with and without the contralateral limb raised. No relationship between measured carpal angle and carpal chip fracture formation existed, suggesting that this group of TB racehorses did not develop carpal chip fractures as a result of calf-kneed conformation. The sample size was small, however, and a larger study may produce different results. Horses with severe calf-kneed conformation may develop other problems and not advance enough in training to develop carpal chip fractures. They may be judged poor surgical candidates, are not referred, or are slow.

Two recent studies evaluated TBs and Quarter Horses (QHs) using skin markers, photography (three views: front, side, back), and computer-image analysis.^{15,16} Of the two studies done in TBs, one evaluated longitudinal development of conformation from weaning to 3 years of age. A strong relationship between long bone lengths and withers heights for all ages supported the theory that horses are proportional. Longitudinal bone growth in the distal limb increased only 5% to 7% and was presumably completed before the yearling year. Withers height, croup height, and length of neck topline, neck bottom line, scapula, humerus, radius, and femur increased significantly from age 0 to 1 year and age 1 to 2 years. Hoof lengths (medial and lateral, right and left) grew significantly from the ages of 0 to 1 and 1 to 2 years but decreased in length from age 2 to 3 years (presumably associated with trimming).¹⁵ Changes in growth measures indicated that growth rate either slowed or reached a plateau at 2 to 3 years of age. Horses also became more offset in the right forelimb between weaning

and age 3, but the offset ratios did not change with age in the left forelimb. Shoulder angle increased in all age groups (becoming more upright), and this contributed to the increase in measured height at the withers. Dorsal hoof angle (both front and hind) decreased significantly from ages 0 to 1 and 1 to 2 years but did not change in the 2- and 3-year-old groups. This study provided objective information regarding conformation and skeletal growth in the TB, which could potentially be used for selection and recognition of important conformational abnormalities.¹⁵ Measurements of length and angle were obtained from photographs in which a tape measure was used for objective criteria and an objective method was developed for measuring offset knees (Figures 4-1 to 4-4).¹⁵

In another study the role of conformation in the development of musculoskeletal problems in the racing TB was evaluated.¹⁶ Conformation measurements were obtained

from photographs of horses with markers at specific reference points and digitally analyzed as previously described.¹⁵ Clinical observations were recorded regularly for each horse, and stepwise (forward) logistic regression analysis was performed to investigate the relationship between binary response of clinical outcomes probability and conformation variables by the method of maximum likelihood. Clinical outcomes significantly ($P < .05$) associated with conformational variables included effusion of the front fetlock joints, effusion of the right carpal joint, effusion of the carpal joints, effusion of the hind fetlock joints, fractures of the left or right carpus, and right front fetlock and left hind fetlock lameness. Offset knees contributed to fetlock lameness (for every 10% increase in the right offset ratio, the risk of effusion in the right front fetlock increased 1.8 times and the odds of right front fetlock lameness increased by a factor of 1.26). Long pasterns increased the odds of forelimb fracture. Surprisingly, an increase in the carpal angle as viewed from the front (carpus valgus) appeared to act as a protective mechanism, because odds for the development of carpal fracture and carpal effusion decreased with increase in carpal angle (for every 1 degree increase in right carpal angle as viewed from the front, the odds of effusion in the right carpus decreased by a factor of 0.68 and the odds of a right carpal fracture decreased by a factor of 0.24).¹⁶ Horses with long shoulders had decreased odds of developing forelimb fracture (odds ratio [OR] = 0.50), but horses with long pasterns had increased odds for forelimb fracture (OR = 4.55). Long sloping pasterns were suggested as a potential cause of carpal chip fractures.¹⁴

In the second TB study described previously, ORs were created for increase in bone length of 2.54 cm (1 inch) or

Fig. 4-1 • Length measurements (centimeters) recorded from the left lateral view in a Thoroughbred conformational study.¹⁵ (Reproduced with permission from Anderson TM, McIlwraith CW: Longitudinal development of equine conformation from weanling to age 3 years in the Thoroughbred, *Equine Vet J* 36:563, 2004.)

Fig. 4-3 • Length (centimeters) and angle measurements (degrees) recorded from the front view in a Thoroughbred study.¹⁵ (Reproduced with permission from Anderson TM, McIlwraith CW: Longitudinal development of equine conformation from weanling to age 3 years in the Thoroughbred, *Equine Vet J* 36:563, 2004.)

Fig. 4-4 • Lines drawn to determine offset ratios. A bench-knee measurement, called an offset ratio, of the medial width/lateral width determines the amount of third metacarpal bone that is offset laterally. The medial/lateral width is the distance (centimeters) from a line drawn along the medial or lateral aspect of the third metacarpal bone to a line from the medial or lateral distal lateral radial physis parallel with the third metacarpal bone. A ratio of greater than 1.0 represents bench-kneed conformation. (Reproduced with permission from Anderson TM, McIlwraith CW: Longitudinal development of equine conformation from weanling to age 3 years in the Thoroughbred, *Equine Vet J* 36:563, 2004.)

joint angle of 1 degree and development of lameness.¹⁶ For every 2.5 cm increase in humeral length, odds for fracture of the proximal phalanx or carpal synovitis or capsulitis increased. Increased length from elbow to ground and increased toe length increased chances for carpal fracture, and in horses with offset knees greater than 10% the potential for carpal or fetlock synovitis or capsulitis increased. The potential for fracture of the proximal phalanx increased with an increase in shoulder angle.¹⁶

A study examining conformation in 160 racing QHs in training at Los Alamitos Race Course found humeral length had a significant association with several clinical entities.¹⁷ For every 10-cm increase in humeral length the odds of an osteochondral fracture fragment of the dorsoproximal aspect of the left front proximal phalanx increased by a factor of 9.06. Similarly, ORs for carpal synovitis and capsulitis and for sustaining carpal chip fracture (8.12 in the left forelimb and 10.17 in the right forelimb) rose significantly with each 10-cm incremental increase in humeral length. The length of the left front toe was important.¹⁷ For each 1-cm increase in toe length, the odds of sustaining carpal chip fractures increased by a factor of 58.90.¹⁷ Horses with upright shoulders were at increased risk for development of osteochondral fragmentation of the

proximal phalanx and those with offset carpi were at increased risk for development of synovitis and capsulitis in both forelimbs (OR = 2.26).¹⁷

The relationship of many lower limb lameness conditions with limb length is interesting and somewhat unexpected because longer limb length generally is considered desirable. In addition, a relationship between longer toes and carpal fracture is interesting. Longer toes may delay breakover of the foot, altering forelimb biomechanics, but an effect on a distant joint such as the carpus cannot be easily explained. The relationship between offset knees and lower limb lameness was expected, but unexpected were fewer carpal fractures in TBs with this conformational fault. Because development of lameness, termed *clinical outcomes* in these studies, is complex, confounding variables such as track conditions, training regimen, breeding, individual horse ability, and experimental error could have contributed to outcome.

Little doubt exists that acquiring objective information is useful, not only to determine what is abnormal but also to define what is normal in a population. In both WBLs and STB trotters in Europe, toed-out conformation in the hindlimbs should likely be considered normal because a majority of both breeds have this conformational trait.^{10,12} These populations differed, however, in forelimb conformation. Few STB trotters had bench-kneed conformation, a finding supported by one of our (MWR) clinical observations that this conformational fault is highly undesirable in this breed (see Chapter 108). Recently, variation in conformation of National Hunt racehorses established guidelines with which individual horses could be compared and highlighted significant variations in horses with different origins (Irish and French horses differed significantly in girth and intermandibular width measurements).¹⁸ Circumference and length measurements were significantly associated with withers height. No underlying pattern of combinations of conformational parameters was found, but variations were identified between left and right measurements and in hoof, stifle angle, and coxofemoral angle measurements.¹⁸

EVALUATION OF CONFORMATION

Conformation determines the way a horse moves, and it is intuitive that a relationship exists between faulty conformation and the development of lameness. Therefore assessment of conformation should be an integral part of lameness examination. Conformation evaluation has four basic components: assessment of (1) balance, (2) lengths, angles, and heights, (3) muscling, and (4) conformation of the limbs. All are intertwined but should be evaluated separately, considering the whole horse not just the limbs, and then consolidated. The clinician should evaluate the horse on firm, level ground, preferably a smooth, nonslip surface that does not obscure the view of the feet. The horse should stand squarely with equal weight on all four limbs. Dynamic assessment of limb conformation while the horse is walking also is essential.

Balance

Balance is the way all parts of the horse fit together and is linked directly with assessment of lengths, angles, and heights. The horse should be proportional and thus well

Fig. 4-5 • Diagrammatic depiction of assessing balance during conformation evaluation. Three circles (from left to right: forehand, midbody, hindquarters) are visualized and should overlap by approximately one third. Excessive overlapping of circles (short coupled) or scant overlapping of circles (long, weak in the back) are common conformational abnormalities. Body length (X) should be equal to or slightly longer than withers height (Y), and withers height and rump height (Z) should be the same.

balanced. A horse may be visualized in thirds—the forehand, the midbody, and the hindquarters—by drawing three circles incorporating these areas (Figure 4-5). The circles should overlap but not excessively. Horses in good balance are likely to be superior athletes. Horses with a short, thick (throatlatch and shoulder regions) neck are often heavy and straight in the shoulders (Figure 4-6). A horse with a short back has naturally closer dorsal spinous processes which may be predisposed to impingement or overriding, whereas a horse with a long back (Figure 4-7) may have difficulty engaging the hindlimbs properly. The clinician must assess the relative heights of the withers and hindquarters. A horse that is taller behind than in front (rump height is greater than height at the withers) is predisposed to forelimb lameness. A horse that also is underdeveloped in the shoulders and upper forelimbs (weak up front) and heavy behind is more at risk. Limb lengths should be proportional to body size and height. In general, the body length (point of shoulder to point of rump) should be equal or slightly longer than withers height (see Figure 4-5).

Head conformation is not relevant to lameness, but the size of the head relative to the body and the angulation between the head and neck influence the ease with which the horse can work “on the bit” (see Chapters 97 and 116). A horse’s ability to see is important. A horse with ocular abnormalities may exhibit bizarre behavioral abnormalities or unusual head and neck carriages, possibly misinterpreted as the result of pain. A rare cause of “being on a line” occurs in driving horses, such as a STB with unilateral

Fig. 4-6 • Horse with short, heavy neck; heavy, short, and straight shoulder; and withers set forward. This horse is prone to forelimb lameness and likely to have a short stride.

blindness. The horse turns the head toward the blind side to see with the opposite eye and thus is on the contralateral line (to straighten the head, the driver must pull on the contralateral line). This mimics a contralateral (to the blind eye) lameness.

Lengths, Angles, and Heights

Body length is important in determining stride length (see [Figure 4-5](#)). Short-coupled conformation predisposes horses to short strides and problems with interference, especially racehorses. If horses are too long, they can be weak in the back. The length of the neck is important in assessing balance and should be proportional to the overall body length. Some horses have long, weak necks. The neck may be “set on low” relative to the shoulder, with a depression (ventral deviation) of the dorsal topline cranial to the withers (ewe necked), giving the appearance of prominent

Fig. 4-7 • Unbalanced Appaloosa gelding that is long and weak in the barrel (back). Rump height is slightly higher than withers height.

withers laid too far caudally. Horses should have adequate depth in the girth region (depth of girth).

Shoulder length (top of the withers to the point of the shoulder) may be related directly to stride length, and horses with longer shoulders usually have longer strides ([Figure 4-8](#)). Those with short shoulders usually have shorter strides (see [Figure 4-8](#)). Shoulder length and shoulder angle often are related; long shoulders often are more sloping (smaller shoulder angle), and short shoulders often are straight. Good shoulder length appears to be important and desirable, but recent objective data from TB and QH racehorses suggest that horses with long limbs may be at increased risk for lower limb lameness.^{16,17}

In TBs particularly a long radius (forearm) and short, strong third metacarpal bone (McIII) have been considered desirable for adequate strength and maximum stride length. However, more recent work¹⁶ suggests that a long forearm would lead to a long metacarpal bone, and because horses are proportional we must question this long-held impression. Chest width should be commensurate with overall body size. A wide chest with a base-narrow forelimb stance (the front feet are close when the horse is evaluated from the front) or a narrow chest with a base-wide stance are undesirable. In STB pacers a good chest width is desirable, but in trotters a narrow chest is preferred (see Chapter 108).

Rump length also is important in determining stride length, and a longer length of the rump is desirable. Many horses with long rumps have larger rump angles (flat croup), and those with short rumps have smaller rump angles (steep croup). Long, flat croup regions are desirable. The ideal

Fig. 4-8 • Measurement of shoulder length (A), rump length (B), shoulder angle (C), and rump angle (D). The pastern angle (E) should be equal to the shoulder angle. Shoulder angle and length are important in determining stride length.

horse should have a long gaskin (crus) and a short, strong metatarsal region (the hocks close to the ground) to maximize stride length.

The angles of the shoulder and rump are important factors in determining stride length and balance. Undesirable shoulder and rump angles often accompany other conformational faults and may predispose to lameness. The ideal angle of the shoulder (relative to the ground) has classically been determined to be 45 degrees (see Figure 4-8). Horses with steep shoulder angles (>50 to 55 degrees) usually have short shoulders and short, upright pasterns, which predispose to lower limb lameness. The forelimb pastern angle should be equal to the shoulder angle. A steep shoulder angle shifts the center of gravity forward, predisposing to forelimb lameness. Horses with a flat rump or croup generally have longer rump lengths and longer strides (Figure 4-9). Horses with short, steep rumps (goose rump) often have short, choppy gaits, and many have hindlimb lameness (Figure 4-10). A steep rump angle shifts the center of gravity caudally, predisposing to hindlimb lameness.

Limbs

It is critical to evaluate limb conformation with the horse standing squarely on a firm, flat surface and with an experienced handler who can make the horse cooperate. If the clinician observes a fault that may result from how the horse is standing, he or she should reevaluate the horse after repositioning. Horses often stand camped out, both behind and in front, simply as the result of improper positioning.

The plumb line concept allows evaluation of each limb from the front or back and the side (Figure 4-11). For example, a vertical line from the point of the shoulder should bisect the limb. The clinician also should evaluate the horse while it is walking because some defects are dynamic. Horses that toe in or toe out, or those with fetlock or carpus varus deformities, may stand reasonably well, particularly with corrective trimming and shoeing,

but the defect may be readily apparent while the horse is walking.

FORELIMB CONFORMATION

Front Perspective

Several forelimb conformational abnormalities are apparent when a horse is evaluated from the front. *Base-wide* conformation may occur alone or in combination with toed-in or toed-out conditions (Figure 4-12). Horses that are base wide stand with the forelimbs lateral to the plumb line and generally are narrow in the chest, resulting in overload of the medial aspect of the lower limb, predisposing to lameness. Horses that are *base wide, toed in* tend to wing out or paddle during protraction (Figures 4-12, B and 4-13, A). Winging out predisposes trotters to interference with the ipsilateral hindlimb. *Base-wide, toed-out* conformation appears most often in horses with uncorrected carpus valgus deformities (Figures 4-12, C and 4-13, B) and results in excessive loading on the medial aspect of the foot and misshapen feet. Interference with the contralateral forelimb may occur in severely affected horses.

Base-narrow conformation may occur alone or in combination with toed-in or toed-out conformation (Figure 4-14). Horses that are base narrow stand with the forelimbs inside each plumb line and overload the outside of the lower limb and foot. Horses that are *base narrow, toed in* tend to wing out, and those that are *base narrow, toed out* tend to wing in during protraction (see Figures 4-13 and 4-14).

With *in-at-the-knee*, knock-kneed, or carpus valgus conformation (Figure 4-15) the carpi are medial to the plumb

Fig. 4-9 • Desirable hindlimb conformation. The flat rump angle and good rump length would likely increase stride length and allow good support and strength of the hindlimbs.

Fig. 4-10 • Undesirable hindlimb conformation characterized by a short, steep rump (goose rump), predisposing to hindlimb lameness.

Fig. 4-11 • Diagram demonstrating use of plumb lines to evaluate limb conformation from three perspectives. Vertical lines are visualized from **A**, the front forelimb (line runs from point of the shoulder, bisecting the limb), **B**, the side forelimb (line bisects elbow joint, carpus, and fetlock joint and intersects the ground approximately 5 cm behind the solar surface of the heel), and **C**, the side hindlimb (line runs from point of rump to the ground, touching the point of the hock and plantar aspect of the metatarsal region and intersecting the ground approximately 7.5 to 10 cm behind the heel) and from **D**, the back hindlimb (line drawn from point of rump, bisecting the hindlimb).

Fig. 4-12 • Three variations of base-wide forelimb conformation, including **(A)** simple base wide, **(B)** base wide, toed in, and **(C)** base wide, toed out.

line, creating an angular deformity and concentrating the weight of the horse on the medial aspect of the carpus and proximal metacarpal region. This condition, if severe, may predispose the horse to carpal lameness and splints. However, recent objective data have suggested that a certain degree of carpal valgus is protective for synovitis and capsulitis, as well as chip fractures in the carpus.¹⁶ Predisposition to carpal lameness and splints with carpal valgus conformation probably applies only to horses with severe abnormalities. In some horses, particularly foals, carpal valgus may be accompanied by external rotation of the entire limb or just the distal aspect (toed out). Severely

affected horses wear the inside aspect of the hoof or shoe abnormally.

Out-at-the-knee (bowlegged, bandy-legged) conformation usually is a consequence of early carpus varus and usually is career-limiting (Figure 4-16). The carpus is bowed outward, lateral to the plumb line. Many horses are also toed in, accentuating abnormal forces on the lateral aspect of the entire distal forelimb, predisposing to osteoarthritis (OA) of the carpus or fetlock or lateral suspensory branch desmitis and sesamoiditis. In most foals with carpus varus, there is coexistent lateral deviation of the elbow, giving the appearance that the angular deformity might be arising

Fig. 4-13 • A, Toed-in conformation often causes horses to wing out or paddle during advancement of the forelimb. **B,** Toed-out conformation causes horses to wing in, predisposing to interference with the contralateral forelimb.

from asymmetrical growth in the physes associated with the elbow joint. Correction is difficult but usually involves transphyseal retardation of the distal lateral radial physis.

Offset or *bench-knee* conformation is classically defined as lateral positioning of the metacarpal region relative to the central axis of the radius (Figure 4-17). However, radiographs demonstrate that the actual displacement usually is at the antebrachiocarpal joint. Displacement may be

unilateral or bilateral with differing degrees of severity on each side. This conformation has been often associated with carpal or metacarpal lameness (Figure 4-18). Many 2-year-old STBs with offset knees are precocious during early training but often develop carpal lameness at 3 or 4 years of age. TBs with offset knees are believed to perform better on the soft turf tracks in Europe, as opposed to the firm turf or dirt tracks in the United States. In recent

Fig. 4-15 • A horse with in-at-the-knee conformation that is worse in the right forelimb.

Fig. 4-17 • Standardbred with a prominently offset (bench) knee in the left forelimb. An apparent lateral deviation or shifting (offset) of the cannon bone and distal extremity occurs relative to the plumb line dropped through the left radius.

Fig. 4-16 • Two-year-old Thoroughbred filly with moderate-to-severe carpus varus (out-at-the-knee) conformation in the left forelimb and mild deformity in the right forelimb. The filly also is toed in, a common finding in horses with this type of conformation. Another common finding is lateral deviation or bowing of the elbow, prompting clinical suspicion that a deformity also exists at this joint.

studies, a relationship between offset knees and carpal lameness was not found, but horses with this conformational abnormality were at risk for fetlock lameness.^{16,17}

Toed-in conformation, or internal rotation of the distal extremity, exists alone or in combination with abnormalities of stance (base narrow or base wide), other conformational faults such as carpus varus and offset knees, and being wide in the chest (see Figure 4-16). Horses that are toed in usually wing out (paddle) (see Figure 4-13). Toed-in conformation is particularly undesirable in a trotter because of potential interference at speed. Toed-in conformation predisposes horses to lateral splints, lameness of the lateral aspect of the fetlock joint region (e.g., lateral branch suspensory desmitis), and OA of the interphalangeal joints. Horses that are toed in wear the outside aspect of the foot.

Toed-out conformation, or external rotation of the distal extremity, is common and if mild may be considered normal or inconsequential (Figure 4-19). Mild toed-out conformation appears in 50% of STBs and is common behind in STBs and WBLs.^{10,12} It first develops in foals and, if pronounced, persists in the mature horse. In foals, toed-out conformation often accompanies carpus valgus deformities but may result from external rotation primarily from the fetlock joint distally or, in more severe deformities, from further proximally (Figure 4-20). Mild toed-out conformation usually resolves as a foal matures and with corrective trimming. Toed-out conformation results in abnormal wear on the inside aspect of the foot. Horses tend

Fig. 4-18 • Dorsopalmar xeroradiograph of 3-year-old Standardbred colt with longitudinal fracture of the third metacarpal bone (*small arrow*). Medial is to the right. The lateral displacement ("step") at the antebrachio-carpal joint (*large arrow*) gives the clinical appearance of an offset (bench) knee.

Fig. 4-19 • Trotter showing inconsequential mild toed-out conformation. Toe weights often are used in trotters to balance gait and correct interference.

to wing in; if winging in is severe, particularly if accompanied by base-narrow conformation, it may interfere with the opposite forelimb (see [Figure 4-13](#)). Exostoses (splints) on the second metacarpal bone (McII) or McIII may develop, requiring protective boots to be worn during exercise. In STB pacers, interference injury occurs as high as the distal aspect of the radius.

Lateral Perspective

Horses camped out in front stand consistently with an entire forelimb ahead of the plumb line, but this conformation usually is a temporary problem with the horse's stance and can be corrected by repositioning the horse, or it reflects pain caused by laminitis, for example. *Camped under in front* is unusual and usually also results from temporary malpositioning of the horse ([Figure 4-21](#)). If a horse prefers to stand camped under and is otherwise sound, however, this trait may be a sign of "extreme speed."¹⁹

Back-at-the-knee or *calf-knee* (sheep-knee) conformation describes a concave dorsal aspect of the limb, with the carpus behind the plumb line ([Figures 4-22 to 4-24](#)). On radiographs of a normal carpus the proximal and distal rows of carpal bones are aligned in a proximal-to-distal direction, and the dorsal faces of these bones are parallel to the radius and the McIII ([Figure 4-23, A](#)). With back-at-the-knee conformation the proximal row of carpal bones is set back ([Figure 4-23, B](#)). Horses that stand back at the knee are considered predisposed to carpal injuries because of the natural tendency of the carpus to hyperextend (larger carpal angle) during fatigue. In our experience, TB racehorses are particularly at risk, despite limited contrary evidence (see page 16).¹⁴ While no associations were made between horses with back-at-the-knee conformation and lameness in recent studies in TBs and QHs, horses

Fig. 4-21 • Diagram showing (A) camped-out in front and (B) camped-under in front conformation, both in relation to plumb lines.

Fig. 4-22 • Thoroughbred yearling with back-at-the-knee (calf-knee) conformation most noticeable in the left forelimb. This conformational fault is undesirable, particularly in racing breeds.

Fig. 4-23 • Lateromedial radiographs of the left carpi of two 2-year-old Thoroughbred racehorses. **A**, There is normal carpal conformation, and the proximal and distal rows of carpal bones are aligned and parallel to the radius and third metacarpal bone. **B**, In a horse with carpal lameness there is palmar deviation of the proximal row of carpal bones. This radiological appearance is typical of back-at-the-knee conformation.

included in those studies were elite, and any foals with obvious back-at-the-knee conformation may have been eliminated from the case population before the studies commenced.^{16,17} In a different study TB foals that were back-at-the-knee improved as they matured from 1, 2, and 3 years of age.¹⁵

In the STB, mild calf-knee conformation is common in pacers and acceptable, whereas in the trotter this defect is undesirable. In other breeds, mild calf-knee conformation may not directly lead to lameness. In young horses with lameness from unrelated sources such as osteochondrosis or fracture of the distal phalanx, back-at-the-knee

Fig. 4-24 • Clydesdale yearling with calf-knee conformation and clubfoot secondary to osteochondrosis of the shoulder joint. This conformation is primarily the result of chronic lameness, decreased weight bearing, and the development of a flexural deformity.

conformation and clubfoot (a small, upright foot) may accompany flexural deformity of the limb (see [Figure 4-24](#)). This deformity is a combination of contraction (clubfoot) and laxity (calf-knee) caused by chronic lameness and partial weight bearing and warrants a guarded prognosis.

Over-at-the-knee, bucked-knee (knee-sprung), or hanging-knee conformation describes a convex dorsal surface of the carpus, with the carpus in front of the plumb line ([Figure 4-25](#)). In young, untrained horses, bucked-knee conformation may be a predictor of lameness, but in mature horses it appears to be an acquired characteristic and occurs primarily in horses that jump. Older cross-country horses, steeplechasers, jumpers, or field hunters are prone to bucked-knee conformation and often stand over at the knee with no obvious lameness. These horses may exhibit a tendency to buck forward to such an extent that they appear on the verge of collapse or prone to stumbling yet show good stability. Lamé horses that stand over at the knee are often found to have pain in the proximal palmar metacarpal area or carpal sheath. *Tied in below the knee* ([Figure 4-26](#)) describes a distinct notch just distal to the accessory carpal bone on the palmar aspect of the limb. Normally, the McIII and the digital flexor tendons are in parallel alignment from the

Fig. 4-25 • Older horse without obvious lameness with over-at-the-knee (bucked-knee) conformation.

Fig. 4-26 • **A**, Diagrammatic representation of tied in below the knee. The dorsal-palmar length of *a* is less than *b*, giving the appearance that the digital flexor tendons run obliquely, proximally to enter the distal carpal region more dorsally than expected. **B**, A horse that is cut-out under the knee has a concave appearance of the dorsal aspect of the distal carpus and proximal metacarpal region (arrow).

accessory carpal bone to the proximal sesamoid bones. With tied-in conformation the digital flexor tendons appear to enter the carpus in a dorsoproximal direction. If the horse also is bucked kneed, the tied-in appearance is accentuated. Young horses are prone to superficial digital flexor tendonitis. In STBs this defect is worse for a pacer than a trotter.

The junction of the carpus and McIII should be flat. *Cut out under knee* describes a notch under the dorsal surface of the carpus (see Figure 4-26). In horses with this defect, the McIII appears thin (dorsopalmar direction) and weak. Horses with this conformational abnormality also are often back at the knee, predisposing them to carpal and metacarpal problems. Some young racehorses, typically late yearlings or early 2-year-olds in training, appear to have distention of the middle carpal joint capsule or an unusually prominent distal radial epiphysis. These findings give the impression of an unusually large gap between these structures, described as “open at the knee.” The first author has not seen a correlation between this clinical observation and obvious radiological changes, although in young horses with this conformation the distal radial physis remains visible. Whether this conformation is relevant to lameness in young racehorses is debatable.

Over at the fetlock usually is seen in young horses with flexural deformity of this joint (see Chapter 59). This conformational fault may persist in a mature horse, causing upright pasterns or knuckling of the fetlock joint. In some horses this condition causes a progressive, permanent deformity and severe lameness, whereas in others a dynamic, intermittent knuckling occurs and some of these horses remain surprisingly sound. Knuckling also may be a sequel to desmitis of the accessory ligament of the deep digital flexor tendon.

HINDLIMB CONFORMATION

Lateral Perspective

Hindlimb conformational faults generally are less numerous and problematic than those in the forelimb because of differences in weight distribution and center of gravity. Plumb lines also are useful in evaluating conformation of the hindlimbs with the horse standing squarely, loading all limbs (see Figure 4-11). Camped-out conformation is unusual and generally results from faulty positioning of the horse during the examination. Horses that are truly camped out usually have short strides and poor athletic ability. Camped under behind often is associated with sickle-hocked conformation but also appears in horses that are straight behind (Figures 4-27 and 4-28). Horses with this type of conformation often have short, choppy strides (Figure 4-29).

A particularly severe conformational fault that leads directly to lameness is *straight behind*, otherwise called *straight hocks* or *post* (posty) leg. Horses that are straight behind have larger stifle and hock joint angles but smaller fetlock joint angles compared with ideal hindlimb conformation (see Figures 4-27 and 4-28). Straight-behind, sickle-hocked, and in-at-the-hock conformation are the three most important hindlimb conformational faults, and all may lead directly to lameness. Horses that are straight behind often develop upward fixation of the patella, a condition seen most often in WBLs. Suspensory desmitis and fetlock OA also occur frequently. Horses with normal initial hindlimb conformation may become straight behind if they develop severe suspensory desmitis and lose support of the fetlock joint (see Chapter 72).

Fig. 4-27 • Diagrammatic representation of conformational faults of the hindlimb from the lateral perspective. Compared with ideal conformation, horses with sickle-hocked conformation (**A**) have a concave dorsal surface of the limb with the distal extremity dorsal to the plumb line, but those that are straight behind (**B**) have large stifle and hock joint angles but smaller fetlock joint angles. Horses that are camped under (**C**) often are sickle hocked as well. Camped-out conformation (**D**) is unusual and most often results from faulty positioning of the horse.

Fig. 4-28 • Standardbred filly with straight hindlimb conformation and suspensory desmitis.

Fig. 4-29 • Horse with camped-under and mild sickle-hocked conformation, a combination leading to a short, choppy gait.

Fig. 4-30 • This 4-year-old Standardbred has sickle-hocked conformation and has developed curb, which has been treated by freeze-firing, resulting in white marks on the plantar aspect of the hocks.

Sickle-hocked conformation is one of the most common conformational faults, and it leads directly to lameness of the tarsus and plantar soft tissues. Horses that are sickle hocked stand with the lower hindlimb well ahead of the plumb line, with an exaggerated concave dorsal surface of the hindlimb (resembling a sickle), creating a smaller than normal hock angle (see [Figures 4-27, 4-29, 4-30, and 4-31](#)). This type of conformation is often called *curby* conformation because horses frequently develop curb (see Chapter 78). Sickle-hocked conformation concentrates load in the distal, plantar aspect of the hock, predisposing to curb and to distal hock joint pain. In a recent study evaluating tarsal angles and joint kinematics and kinetics, horses with large hock angles (straighter behind) had less absorbed concussion during impact, smaller vertical impulse, and less extensor movement, characteristics thought to predispose these horses to OA.²⁰ One of us (MWR) feels results of this study could be interpreted differently, since clinical experience contradicts this finding; horses with larger hock angles are at less risk of the development of OA of the distal hock joints and less absorbed concussion by the tarsus may make other structures such as the suspensory ligament at risk of injury. However, smaller net movement in horses with larger hock angles may be protective for the development of plantar tarsal

Fig. 4-31 • Hindlimb conformational abnormalities viewed from the rear. **A**, Cow-hocked conformation is a common fault characterized by external rotation of the limb, usually without angular deformity, causing the hocks to be too close together. Mild external rotation of the hindlimbs is common and does not appear to cause lameness. **B**, Cow-hocked, base-narrow conformation. **C**, Base-narrow conformation. **D**, Base-wide conformation is uncommon. **E**, Bowlegged conformation is uncommon and undesirable.

conditions such as curb, a finding that correlates well with my clinical impressions.²⁰ In foals with incomplete or delayed ossification of the tarsal bones, marked sickle-hocked conformation may occur (see Chapters 44 and 128). Sickle-hocked conformation is undesirable, particularly in racing breeds, but if mild is not detrimental. In STB pacers, some prefer a mild degree of sickle-hocked conformation because horses can extend the hindlimbs farther forward without risk of interference. In STB trotters the condition often predisposes to distal hock joint pain and curb, but these horses tend to be fast, although unsound. In Western reining horses, sickle-hocked horses may be better able to perform sliding stops.

Rear Perspective

A majority of STB and WBL horses toe out behind, which should be considered normal. Horses with mild external rotation of the distal extremity are said to be toed out and usually also have external rotation of hocks, causing the points of the hocks to be closer than normal. This fault is called *cow-hocked* conformation and is a *rotational* change of the hindlimb (Figure 4-31). Cow-hocked conformation occurs in combination with base-wide or base-narrow deformities or independently. Cow-hocked and base-narrow conformation is most common. Base-wide and base-narrow conformation may occur without cow-hocked conformation. These conformational faults seldom lead to lameness but have a substantial effect on gait in some horses. Horses that are base narrow travel closely behind, particularly at a walk. Some travel closely at a trot, pace, or gallop, whereas others seem to widen out when going faster, thus avoiding interference. Those that travel closely at speed often interfere, causing injury to the medial aspect of the contralateral hindlimb.

Fig. 4-32 • Mature Standardbred racehorse with in-at-the-hock (tarsus valgus) conformation. This conformational abnormality is characterized by an angular deformity as opposed to the rotational deformity seen in cow-hocked conformation. The characteristic white marks were produced by cryotherapy for treatment of bilateral curb.

Bowlegged hindlimb conformation, in which the point of both hocks is truly outside the plumb line, is uncommon (see Figure 4-31). Occasionally horses that are base narrow appear to be bowlegged. Unilateral bowlegged conformation occurs in foals born with windswept deformity or in those with tarsal varus deformity. Bilateral tarsal varus deformity is unusual.

In at the hock or tarsus valgus is an *angular* deformity (see Figure 4-32). The deformity can be corrected in foals. If it persists in a mature horse, particularly a racehorse with other conformational abnormalities, such as sickle hocks, abnormal forces or load occur in the tarsal region, predisposing the horse to distal hock joint pain, curb, and proximal metatarsal lameness.

Horses can be toed in or toed out behind, but in general the conformational abnormality starts above the fetlock joint, causing the lower limb abnormality to be linked with the upper limb. Thus a horse that is toed in generally is bowlegged, and one that is toed out is cow hocked. In some foals, however, fetlock varus occurs independent of upper limb conformational abnormalities. This abnormality usually appears in windswept foals in which upper limb deformities have resolved, leaving a fetlock varus. This is an angular deformity, but with abnormal hoof wear, toed-in conformation can develop. Fetlock varus and the resulting toed-in conformational defect may cause OA of the fetlock and interphalangeal joints and can be career-limiting.

CONFORMATION OF THE DIGIT

More detailed aspects of conformation of the foot and limb flight characteristics are discussed in Chapters 5, 7, and 27. Many of the changes in hoof growth or conformational changes in the hoof are the result of wear, shoeing, and exercise demands of training and performance and often are not present in a young horse.

The pastern angle has traditionally been thought to be similar to the angle of the shoulder (see Figure 4-8). However, in the recent TB study front pastern angle was only mildly correlated to the scapular spine angle, and there was variability.¹⁵ Variability was likely from shoeing and lowering of the heel. There was a good correlation between pastern and hoof angles.¹⁵ The foot-pastern axis should be straight. The pastern should be neither excessively sloped (low angle) nor upright (high angle). The angle of the pastern is important in determining the amount of load on the lower limb structures. In general, the more upright the pastern (steeper pastern angle), the shorter the stride and vice versa. Horses with upright pasterns appear to be prone to foot lameness and perhaps superficial digital flexor tendonitis. Those with long, sloping pasterns may be at risk to develop OA of the fetlock joint and proximal phalangeal fractures. Horses with short, upright pasterns but relatively normal hoof angles have a broken foot-pastern axis—the foot axis is lower than the pastern axis—and are at risk for developing foot lameness (Figure 4-33). Horses with broken back foot-pastern axis often have underrun heels and other hoof abnormalities and should be evaluated for corrective trimming if lame. If the pastern axis is lower than the foot axis (broken forward foot-pastern axis), called *coon-footed*, it causes undue strain on the soft tissue structures supporting the fetlock joint. This type of conformation may result from severe suspensory desmitis and loss of support of the fetlock joint.

Pastern length is important and usually is related to pastern angle. Horses with long pasterns commonly have more slope or lower pastern angles. The plumb line should drop approximately 5 cm behind the heel in a well-conformed horse. In horses with long, sloping, and weak pasterns, the line drops more than 5 cm behind the heel. Those with short pasterns usually have more upright pasterns, and the plumb line drops through the foot. A variety of pastern lengths and angles occur, but the pastern length should be in proportion to the overall length of the limb.

Fig. 4-33 • Diagrammatic representation of ideal pastern and foot conformation and the concept of a broken pastern-foot axis. Ideally the foot and pastern angles (**A**) should be identical to allow full and even weight bearing on all aspects of the foot. A broken foot axis (**B**) occurs when pastern angle is more upright than that of the foot or vice versa (**C**). In both latter situations, uneven load distribution on the foot or soft tissue structures may cause lameness.

Viewed from the front, the plumb line may divide the pastern and foot asymmetrically with more pastern and foot laterally, which often is associated with some degree of distortion of the hoof capsule, with a steeper medial wall and some flaring laterally. This results in asymmetrical loading of the distal limb joints and may predispose to lameness.

Buttress foot is an acquired firm bulge or swelling at and proximal to the dorsal aspect of the coronary band and usually reflects OA of the distal interphalangeal joint (sometimes called *pyramidal disease*). *Bull-nose foot* conformation, an abnormal convex dorsal hoof wall, is uncommon but is occasionally seen in a hind foot (Figure 4-34). It is possible to cause this abnormal hoof conformation by incorrect trimming of the dorsal hoof wall, but in most horses it is caused by faulty hoof growth. One of us (MWR) has seen this type of abnormal hind foot conformation most commonly in the TB racehorse, and it is possible there may be a relationship between bull-nose hoof conformation and lameness of the digit or other areas of the distal aspect of the hindlimb. There may be a relationship between bull-nose foot conformation and long, weak pasterns (see Figure 4-34).

Fig. 4-34 • Bull-nose foot conformation in a 3-year-old Thoroughbred racehorse that developed a medial condylar fracture of the distal aspect of the third metatarsal bone requiring surgical repair. The relationship between poor hoof conformation and lameness is unknown, but in this horse long, weak pasterns are seen and the combination of conformational faults may predispose horses to injury.

Chapter 5

Observation: Symmetry and Posture

Mike W. Ross

Assessments of symmetry and posture are important aspects of a lameness examination. Comparison between the normal and abnormal sides facilitates identification of abnormalities, unless the condition is bilateral so that no recognizable differences exist between the left and right limbs. The horse should be standing squarely on a flat surface in a quiet, insect-free environment. Horses with severe lameness often are reluctant to stand correctly, but information gained about symmetry and posture of severely lame horses is valuable. The veterinarian should look carefully at size, shape, contour, heights, and widths and compare with the opposite side.

FORELIMB SYMMETRY

Muscle Atrophy

The symmetry of skeletal muscle in the forearm, pectoral, and cervical areas should be assessed. Muscle atrophy that occurs in horses with chronic lameness conditions is called *disuse atrophy* and in those with neurological disease is called *neurogenic atrophy*. Horses with muscle atrophy and lower motor neuron disease (see Chapter 11) may be lame, sometimes as a result of muscle pain or nerve root pain,

complicating differentiation between these causes of muscle atrophy. In most but not all horses with neurogenic atrophy, other clinical signs suggestive of neurological disease may be present. Horses with disuse atrophy resulting from chronic lameness usually have generalized atrophy of the ipsilateral forelimb. Muscle loss usually is not pronounced but involves the forearm (extensors are most commonly affected), triceps, and shoulder muscles. Shoulder muscle atrophy involving the infraspinatus and supraspinatus muscles generally is not pronounced, and lateral subluxation of the shoulder joint during weight bearing is not present (see Chapter 40).

Development of disuse atrophy resulting from chronic lameness generally takes weeks to months unless severe lameness exists. In horses with severe or non-weight-bearing lameness, atrophy may develop within 10 to 14 days. In horses with severe forelimb lameness, carpal contraction (flexural deformity of the carpus) may occur simultaneously with muscle atrophy. The most common causes of carpal contraction because of ipsilateral forelimb lameness are olecranon fracture and other elbow lameness, but carpal contraction may occur in horses with severe shoulder or even lower limb lameness. Atrophy of the triceps muscles usually is recognized before other muscle atrophy in severely lame horses.

Horses with neurogenic atrophy may have profound atrophy of one or more muscles in the forearm, pectoral, or cervical regions. Atrophy often is much more pronounced than expected based on the degree of lameness, prompting suspicion of neurological disease. Pronounced, unilateral pectoral or triceps atrophy with mild atrophy of the forearm muscles suggests neurological disease. Severe atrophy localized to the infraspinatus or supraspinatus muscles without subluxation of the shoulder joint usually results from injury of the suprascapular nerve caused by

external trauma. Atrophy and subluxation of the shoulder joint is associated with injury of the brachial plexus or nerve roots. Other muscles may also show atrophy.

Localized muscle atrophy or fibrosis occurs in horses with previous injury and subsequent scar tissue formation within muscle bellies. This condition is more common in the hindlimb but occasionally occurs in the forelimb.

Swelling

Swelling, a common sign of inflammation, often causes asymmetry. The presence of swelling and heat should alert the lameness diagnostician to the possibility of an infectious process and may lead to additional examinations such as assessment of body temperature and the acquisition of laboratory data. Swelling within a joint capsule caused by excess joint fluid, *effusion*, is a general reaction of the joint to several traumatic or degenerative processes. Edema, cellulitis (lymphangitis), bleeding, and fibrosis can cause soft tissue swelling. Underlying bony enlargement can mimic soft tissue swelling, particularly in older horses with advanced osteoarthritis. Some swellings are clinically innocuous, such as mild distention of a digital flexor tendon sheath (so-called “windgalls” or “wind puffs”), but a recent change in size, local heat, or marked left-right asymmetry should alert the clinician to a possible problem. Occasionally a well-circumscribed tense spherical swelling is seen palmar to the neurovascular bundle on the side of the fetlock. These synovium-filled masses are usually incidental findings of no clinical significance. *Edema* usually signals acute inflammation, and pits (a distinct impression is visible) when compressed by digital palpation (pitting edema). Horses develop edema around and often distal to the site of inflammation. In some horses, especially racehorses left unbandaged when accustomed to being bandaged, benign mild-to-moderate edema of the distal extremities develops. This process is called “stocking-up” and should not be misinterpreted as a pathological process. In these horses the edematous area is not painful and usually does not pit, and the horse is not lame. Edema in these horses can complicate lameness examination because it is sometimes difficult to palpate underlying structures and to perform diagnostic analgesia.

Cellulitis describes infection within the tissue planes of the distal extremities (see Chapter 14) and is sometimes called *lymphangitis*. Lymphangitis, by definition, is inflammation of the lymphatic circulation of the limb, but the conditions are similar and the terms are used interchangeably. Swelling is firm, warm, and painful, and lameness is often pronounced. “Stovepipe” swelling describes this condition (“the horse is all stoved-up”). Horses generally show systemic signs such as fever and elevated white blood cell count. Cellulitis usually results from small puncture wounds that may be difficult to discover or occurs after articular, periarticular, or subcutaneous injections. Infection develops in subcutaneous tissues or deeper in the dense fascial planes and can be difficult to eradicate.

Blunt trauma or fractures may cause bleeding within tissue planes. Severe lameness and swelling accompany fractures of the scapula and humerus, because large vessels are nearby. Bleeding may be severe and cause a decrease in plasma protein and packed blood cell volume values. In horses with fractures located more distally in the limb, swelling is less pronounced but still prominent. The most

likely location of injury is the swollen area, but swelling may occur distal to the site of injury because of venous and lymphatic congestion.

Fibrosis or scar tissue formation as the result of previous cellulitis or trauma causes asymmetry of the distal extremities but may not be the source of the current lameness. The veterinarian should avoid overinterpreting areas of scar tissue formation unless evidence of recrudescence of inflammation exists. Horses may have scars caused by previous application of counterirritants or from healed wounds, leaving large, painless, and thus benign blemishes. Scars from previous surgical procedures, sometimes recognized by small areas of white hair accumulation, should be noted but may have no bearing on the current problem. Previous scars may have more relevance during prepurchase examinations.

Bony swelling is a common cause of asymmetry. Proliferative change results in periosteal or periarticular new bone formation and accompanies myriad problems in the distal extremities. Bony changes may be active, causing the current lameness problem, or old and inactive, causing few or no clinical signs. For example, old inactive bony swelling of the shin or osselets (bony and fibrous swelling of the fetlock joint) may be prominent in ex-racehorses but may have little to no relevance to current lameness.

Angular Deformity

Angular limb deformities in young horses are common, are sometimes associated with lameness or other developmental orthopedic disease, and are discussed elsewhere (see Chapter 58). Abnormalities of conformation should be noted but may have little relevance to the current lameness problem (see Chapter 4). Horses younger than 2 years of age with severe forelimb lameness of several months' duration may develop contralateral varus deformity originating from the carpus or elbow joints.

Horses with severe lameness usually caused by trauma may have luxation or subluxation of joints as a result of collateral ligament injury or fractures and may have an acute change in limb angulation. Angular deviations of limbs are unusual in older horses and generally signal severe injury. Visual examination should be followed by careful palpation during which varus and valgus stress is applied to joints. Stress radiographs can be useful to determine collateral ligament integrity.

Foot Size

Ideally both front feet should be identical in size and shape, or nearly so, and any asymmetry should be noted. Horses with chronic lameness may have disparity in foot size, usually with the smaller foot being ipsilateral to lameness. The small foot often is contracted and more upright (Figure 5-1). Chronic reduction in weight bearing results in foot size disparity in some, but not all, horses. Mild disparity in foot size is a normal finding in some horses. Mild clubfoot conformation, acquired from previous flexural deformity, may be present incidentally in adult horses. Previous lameness may have caused contraction of the foot but has since resolved, resulting in disparity in foot size and shape but no residual lameness. In these horses it would be a mistake to assume current lameness is originating from the foot without confirmation using diagnostic analgesia. Clubfoot conformation appears to be better

Fig. 5-1 • A horse with disparity in front foot size caused by chronic lameness. The right forelimb foot is smaller compared with the normal left forelimb foot when viewed from the front (**A**) and more upright when viewed from the side (**B**).

tolerated in Thoroughbred (TB) than in Standardbred (STB) racehorses.

Fetlock Height

Fetlock position should be assessed in the standing horse and during movement. In a standing horse, fetlock height should be symmetrical, assuming the horse is loading the limbs equally. Horses with severe lameness commonly “point” or hold the limb in front of the opposite forelimb, thus taking weight off the limb. This standing posture obviously causes disparity in fetlock height but should be carefully interpreted. Loss of support of a fetlock in the standing horse causes the affected fetlock to drop and occurs most commonly with acute, traumatic disruption of the suspensory apparatus in racehorses but also appears with chronic, active desmitis (Figure 5-2). Severe superficial digital flexor tendonitis or lacerations resulting in fiber

Fig. 5-2 • Standardbred racehorse with severe suspensory desmitis and a “dropped fetlock.” The level of the right front fetlock joint is lower than that of the left front, caused by chronic, severe desmitis. Similar clinical signs and severe lameness appear in horses with acute traumatic disruption of the suspensory apparatus.

damage of the deep or superficial digital flexor tendons can cause similar clinical signs.

In horses with mild flexural deformity of the metacarpophalangeal joint, dynamic knuckling (buckling forward, flexion) of the fetlock joint may occur in the standing position (Figure 5-3). Joint position usually returns to normal during movement. In horses with severe flexural deformity, normal fetlock position is never achieved. Knuckling of the fetlock also may result from desmitis of the accessory ligament of the deep digital flexor tendon.

Scapular Height

Disparity in scapular height is a rare clinical sign in a lame horse. The veterinarian must stand behind and above the horse to observe scapular height. The horse’s mane may obscure observation from a distance, requiring closer examination by palpation. Traumatic or neurological conditions affect scapular height, causing either injury or dysfunction of the serratus ventralis muscle, respectively. With both conditions the dorsal aspect of the scapula is *higher* on the affected side. The veterinarian may place pieces of white tape or other suitable markers on both sides of the horse and stand back to compare height or may use two assistants to point to the locations. Horses may have disparity in scapular height unrelated to the current lameness condition if there has been resolution of the original injury or neurological problem. Care must be taken to differentiate between genuine differences in the height of each scapula and asymmetrical musculature,

Fig. 5-3 • Knuckling forward of the right front fetlock joint occurs in a standing position in this horse with mild flexural deformity of the metacarpophalangeal joint. This dynamic instability abates somewhat when the horse moves, but the left front fetlock also is straight, indicating the presence of bilateral flexural deformity.

which occurs much more commonly and may be an incidental observation. Horses with disparity in scapular height or asymmetrical muscle development may have problems with saddle fit.

HINDLIMB SYMMETRY

Muscle Atrophy

Asymmetry of bone and muscle mass in the hindlimbs and pelvis is a common clinical sign but must be differentiated carefully. The horse should stand squarely on a flat, even surface. The clinician must determine whether asymmetry exists, and if so, if the problem involves muscle, bone, or a combination of the tissues. Muscle atrophy is most common and, if unilateral muscle atrophy exists, easily can be confused with bony asymmetry caused by pelvic fractures or asymmetry of the tubera sacrale.

Disuse and neurogenic muscle atrophy occur in the hindlimb. Horses with chronic hindlimb lameness develop ipsilateral gluteal muscle atrophy, but asymmetry may be subtle. Mild muscle atrophy usually first appears just lateral to a tuber sacrale. The veterinarian should differentiate muscle atrophy from disparity in height of the tubera sacrale (Figure 5-4). Recognition of muscle atrophy helps determine the lame leg and provides some information about the duration of the problem. Severe muscle atrophy develops in horses with long-standing, severe lameness or in those with neurological disease (Figure 5-5).

In horses with neurogenic atrophy of the gluteal muscles the degree of muscle loss is inappropriately severe compared

Fig. 5-4 • Three-year-old Thoroughbred filly with subtle disparity in tubera sacrale height. The left tuber sacrale is slightly lower (arrow) than the right, caused by a fracture at the base of the tuber sacrale. This clinical finding can easily be missed or confused with mild muscle atrophy.

Fig. 5-5 • A 4-year-old Standardbred with severe left gluteal atrophy caused by neurological disease. The presumptive clinical diagnosis was equine protozoal myelitis.

with observed lameness. Neurological signs such as weakness and proprioceptive deficits usually appear in horses with neurogenic atrophy, but early in the course of diseases such as equine protozoal myelitis (EPM) the only observable signs may be muscle atrophy and mild lameness.

Selective atrophy of individual muscles or muscle groups occurs in horses with neurological disease or injuries causing focal muscle loss and scarring. Horses with trauma involving fracture of the tubera ischii may develop focal muscle loss of the semitendinosus or semimembranosus muscles. A depression, sometimes subtle, resulting from localized muscle atrophy replaces initial swelling of the point of the rump. Horses with *fibrotic myopathy*, which in most horses is believed to result from injury and scarring of the semitendinosus muscle, usually have palpable scars or defects of the caudal thigh muscles. Degenerative neuropathy of the nerves supplying the distal aspect of the semitendinosus muscle also may cause fibrotic myopathy¹ (see Chapter 48).

Swelling

Swelling is especially important in horses with acute, severe lameness when the clinician must differentiate between catastrophic injury, such as pelvic or long bone fracture, and more common conditions, such as cellulitis. Horses with pelvic fractures may develop mild swelling in the thigh, but swelling is not prominent in most horses. In horses with fracture of a tuber coxae or ilial wing or shaft, mild swelling may develop distally but usually is not prominent. Inappropriate lameness and lack of swelling should prompt the clinician to perform a rectal examination, checking for internal asymmetry or crepitus. Horses with femoral fractures develop acute, severe swelling of the thigh, accompanied by severe lameness, instability, and often crepitus (Figure 5-6). Horses may develop severe swelling of the stifle and thigh resulting from trauma and secondary bleeding. Large stifle hematomas resemble the swelling in horses with femoral fractures, and in some

horses hematomas can be confused with severe femoropatellar effusion (Figure 5-7). Excessive bleeding from subcutaneous vessels also may involve the ventral, lateral abdominal region. In horses with stifle hematoma, lameness may not be as prominent as expected, and swelling

Fig. 5-6 • A Thoroughbred broodmare with severe lameness and swelling of the left thigh caused by a comminuted femoral fracture.

Fig. 5-7 • Moderate, fluctuant soft tissue swelling over the stifle caused by subcutaneous bleeding (hematoma). In this situation, swelling is much more pronounced than expected for the observed degree of lameness.

fluctuates, which is useful in differentiating this cause of lameness from femoral fractures. Generalized, diffuse soft tissue swelling appears in horses with cellulitis or lymphangitis in the hindlimb (Figure 5-8). Horses that negotiate fences such as event and timber horses are at risk for stifle-region trauma and swelling.

Bony Asymmetry

Comparison of the height of the tubera coxae is important to determine the nature and extent of pelvic bony injury (Figure 5-9). Two assistants, one on each side of the horse, may point to the dorsal aspect of the tubera coxae, or the veterinarian may use temporary markers to compare the height. Determining the height of the tubera sacrale may be difficult and requires careful palpation to differentiate bone, ligament, and muscle asymmetry. Accurate determination may be possible only by ultrasonography. Estimating the midline-to-lateral pelvic width also aids in diagnosing acute or chronic pelvic fractures.

Tubera Coxae

Asymmetry in height of the tubera coxae accompanies many different pelvic fractures. The most common fracture involves the tuber coxae itself, often called *knocked-down hip*. Marked ventral and medial displacement of the fracture fragment occurs because of muscle attachment to the bony prominence. The veterinarian also must palpate the actual shape of the tuber coxae, because ventral displacement occurs with other pelvic injuries. Displacement and

rotation occur in horses with fracture of the wing of the ilium caudal to the tuber coxae without an obvious change in size or shape of the tuber coxae. However, with a partial fracture of the ventral aspect of the tuber coxae, there is a change in its shape without displacement of the dorsal aspect of the bone.

Tubera Sacrale

The term *hunter's bump* describes the prominence of the tubera sacrale. This finding may reflect the horse's conformation, poorly developed surrounding musculature, or a change in position of one or both tubera sacrale. Increase or decrease in size of the overlying dorsal sacroiliac ligament also results in apparent asymmetry. Many clinically normal horses have slight apparent asymmetry of the tubera sacrale. Asymmetry in height of the tubera sacrale occurs in horses with acute or chronic sacroiliac joint disruption (Figure 5-10). In horses with acute fractures of the base of the tubera sacrale, the affected side is lower² (see Chapters 49 and 50). Ultrasonography and nuclear scintigraphy may help identify the cause of asymmetry.

Midline-to-Lateral Pelvic Width

A change in the relative width of each hemipelvis is a subtle but important clinical sign of pelvic injury. In most horses with pelvic fractures, the injured side is narrower than the normal side. Overriding and displacement of fracture fragments result in compression on the injured side.

Fig. 5-8 • Soft tissue swelling caused by cellulitis. Firm, painful swelling appears in the entire limb.

Fig. 5-9 • A horse that is well positioned for determination of tubera coxae height and the midline-to-lateral pelvic width (X , Y). In a normal horse, $X = Y$.

Fig. 5-10 • Asymmetry of the tubera sacrale. The left tuber sacrale (*arrow*) is higher than the right. This horse has chronic left sacroiliac subluxation.

Swelling over the Greater Trochanter

Mild swelling over the lateral aspect of the coxofemoral joint may be a subtle clinical sign of acetabular or proximal femoral fractures. When standing behind the horse, the veterinarian should carefully observe for enlargement over the affected hip joint. This clinical sign usually is not noticeable initially, but soft tissue enlargement is visible within 2 to 3 weeks after intraarticular fracture. The groove between the greater trochanter and the biceps femoris muscle should be compared carefully; usually a slight bulge or subtle enlargement on the affected side is visible.

Crepitus

Bone-on-bone grating is a valuable clinical sign, particularly in horses with pelvic injury. Crepitus can be heard (with or without a stethoscope) or felt (external or rectal palpation) and most often is caused by movement of bone fragments in horses with displaced fractures (see Chapter 6). In horses with pelvic fractures, crepitus usually is not observed for several days to weeks after injury because muscle tone and fracture hematoma apparently stabilize fracture fragments and delay onset. Crepitus also can be felt or heard in horses with end-stage osteoarthritis.

Calcaneus

The points of the hock should be of equal height when observed from the side or from behind. There is dramatic lowering of the point of the hock with complete disruption of the common calcaneal tendon or gastrocnemius tendon alone. Partial injury of the gastrocnemius muscle origin, the musculotendonous junction, or the tendon itself causes varying degrees of asymmetry in height of the point of the hock, both in a standing horse and during movement.³ Other gait abnormalities such as unusual rotation or instability of the limb usually are present (Figure 5-11).

The point of the hock is elevated in horses with severe pelvic fractures involving the acetabulum, luxation of the coxofemoral joint, and some femoral fractures (Figure 5-12). Evaluating elevation is difficult because horses with severe lameness usually cannot bear weight, causing a dramatic alteration in limb position. However, in horses with true elevation in the point of the hock, the hock is extended,

Fig. 5-11 • A horse with partial disruption of the left gastrocnemius. An injury to the origin of the lateral head of the gastrocnemius muscle in this horse caused an unusual gait deficit, lameness, and mild distal displacement (drop) of the hock and fetlock.

Fig. 5-12 • A horse with a comminuted fracture of the left femur. The point of the left hock is higher than that of the right as a result of overriding of fracture fragments and muscle contraction, effectively shortening the limb.

Fig. 5-13 • Warmblood gelding with chronic, severe, bilateral hindlimb suspensory desmitis causing noticeable fetlock drop in the left hindlimb.

whereas with most non-weight-bearing conditions, the hock is flexed.

Fetlock Height

Assessment of fetlock position is as important in the hindlimb as in the forelimb. Horses with excessively straight hindlimb conformation (straight hocks) may have more obvious excursion of the fetlock (fetlock drop) while moving or shifting position during standing. Pathological fetlock drop generally accompanies suspensory desmitis (Figure 5-13) but also occurs with partial disruption of the gastrocnemius and other ligamentous and tendinous injuries.

POSTURE

Body posture provides important clues to the source of lameness, but some abnormalities may be missed unless the horse is observed over long periods. Normal horses tend to rest one hindlimb and may alternate between limbs. Resting a forelimb is uncommon but does occur. Distractions in the environment may make a horse stand normally despite pain. However, abnormal posture because of mechanical or neurological dysfunction usually is evident.

The horse has a well-developed stay apparatus in both the forelimbs and hindlimbs.⁴ It is assumed that the main purpose of the stay apparatus is to allow the horse to remain standing for long periods. The stay apparatus in the hindlimbs is better developed than in the forelimbs and includes ligamentous and tendinous structures dictating predictable movement of joints in the limb. If intact, the hindlimb stay apparatus demands reciprocal movement of the hock and stifle and often is called the *reciprocal*

apparatus. A change in posture usually means a part of the reciprocal apparatus is broken.

FORELIMB POSTURE

Pointing

Horses that are severely lame often point or hold the affected forelimb ahead of the unaffected forelimb, or the least affected forelimb in horses with bilateral pain. These horses usually are severely lame at a walk. Horses with severe, bilateral forelimb lameness caused by laminitis may stand camped out in front, attempting to point with both forelimbs simultaneously. However, pointing is not synonymous with the presence of pain or lameness or its degree. Some horses prefer to point one forelimb or another and walk and trot normally. In general, pointing is unusual and often signals resting pain or subtle pain relieved by adopting this posture. Some horses stack bedding under the heel of one or both front feet to stand in a toe-down position, indicating a degree of unilateral or bilateral foot pain. These horses often are not as lame as expected based on the degree of postural change seen at rest. Alternatively a horse may stand with its hindquarters “sitting” on a manger partially to unload the front feet.

Treading

Constant shifting of weight from one forelimb to the other may indicate bilateral forelimb lameness. Laminitis, severe soft tissue injuries such as tendonitis or suspensory desmitis, or severe osteoarthritis may cause treading. Horses with chronic, severe unilateral forelimb lameness often stand with little weight on the affected limb, overload the unaffected limb, and seldom tread. The development of treading in such circumstances is an ominous sign because the horse now is trying to shift weight from the previously unaffected limb, probably because of laminitis.

Buckling Forward at the Knee

Horses with bucked-knee or over-at-the-knee conformation may buckle forward at the knee while standing. In clinically normal older field hunters or other heavily used riding horses with bilateral over-at-the-knee conformation, this may be particularly obvious. The carpus is locked in extension primarily by the action of the extensor muscles. Neurological disease (e.g., EPM) affecting forelimb extensor muscles is a rare cause of buckling forward at the knee, both at rest and during movement. Specific injury of the distal aspect of the radial nerve causes similar clinical signs. In foals, rupture of the common digital extensor tendon or other extensor tendons may cause this posture (see Chapters 77 and 128).

Dropped Elbow

A dropped elbow results from failure of the triceps apparatus to maintain elbow extension (Figure 5-14) and usually results from fracture of the olecranon process. It also may result from injury to the radial nerve or brachial plexus. Similar clinical signs appear in horses with lesions of the nerve roots (neuritis, radiculopathy) or nerve cell bodies in the cervical intumescence, usually the result of lower motor neuron disease. A most unusual cause of this posture appears in horses with root signature (see the section on [neck pain](#)).

Fig. 5-14 • Classic forelimb posture most often called *radial nerve paresis* or *paralysis*. The horse cannot extend or fix the elbow, causing the appearance of dropped elbow. The inability to fix the elbow (loss of triceps apparatus) commonly occurs in horses with olecranon fractures.

Severe Lameness of the Shoulder Region

Horses with severe shoulder pain may stand with the affected limb more caudal than usual (Figure 5-15) and often drag the limb with even the slightest movement. This posture is similar to dropped-elbow posture, but in horses with a dropped elbow the limb is held at, or even slightly cranial to, the expected position.

Neck Pain

Horses with neck pain often hold the head and neck lower than expected, at a level equal to or slightly lower than the withers (Figure 5-16). Historically some horses may be observed to get caught in this position. In horses with severe pain, muscle tremors or spasms are visible, especially when one approaches the horse or the horse moves; the horse may stand in a guarded position. The horse may be reluctant to turn or move and may be unable or unwilling to eat food from either the ground or an elevated position. An unusual but characteristic sign of neck pain is posturing of a single forelimb, usually on the side of the lesion. The limb is held extended or pointed in front of the other forelimb; rarely the limb is held in slight flexion (see Figure 53-10, A). This sign appears in dogs with cervical pain, most commonly from intervertebral disk disease, and is termed *root signature*.^{5,6} Pain associated with the nerve roots supplying the brachial plexus may be the cause. Such a

Fig. 5-15 • Forelimb posture in a foal with osteomyelitis (scapula) and infectious arthritis (shoulder joint). With severe lameness of the shoulder or bicipital bursa, horses are reluctant to stand or move normally and often hold the limb caudally. This posture may be difficult to differentiate from that seen with loss of the triceps apparatus (see Figure 5-14).

Fig. 5-16 • Yearling Standardbred with neck pain on the left side showing typical stance and head and neck posture.

posture has also been seen in a horse with a mediastinal abscess. Some horses with cervical pain also have unilateral forelimb lameness.⁷

HINDLIMB POSTURE

Resting a Hindlimb

Normally a horse rests one hindlimb or another, but immediate resting of a hindlimb after work, or a combination of resting of the hindlimb and trembling in the flank or stifle region, may indicate lameness. Resting of the hindlimb, particularly with trembling of the quadriceps muscles, often prompts handlers to erroneously assume the horse has stifle region pain. Horses with hindlimb pain from other locations will often assume this posture.

Abnormal Tail Position

Horses may carry the tail in an abnormal position during movement, often alerting an observer to possible hindlimb pain. The tail usually is carried away from the lame limb, but this finding is inconsistent. Horses seldom have an abnormal tail posture at rest unless the tail has been traumatized or set or there is severe hindlimb lameness.

External Rotation of the Hindlimb

Cow-hocked conformation is common, but unilateral external rotation may reflect pelvic injury (Figure 5-17). The veterinarian should verify this change in posture by moving and reevaluating the horse. Horses with pronounced unilateral external rotation usually have fractures of the acetabulum or the proximal aspect of the femur but may have nonarticular ilial shaft or wing fractures.

Hindlimb Varus Posture

Horses with chronic, severe unilateral hindlimb lameness may develop varus conformation of the contralateral limb (see Figure 5-17). This posture most often appears in foals and may develop 7 to 10 days after onset of lameness.

Treading

Constant shifting of weight between the hindlimbs, or treading, is an unusual clinical sign and usually indicates pronounced bilateral lameness. Horses with bilateral hindlimb laminitis or severe osteoarthritis of any joint may tread. Horses with chronic, severe unilateral hindlimb lameness can endure 4 to 6 weeks or more of weight bearing on the contralateral limb, but treading may be the earliest sign of traumatic laminitis in the supporting limb.

Camped Under

Camped under appears only in horses with bilateral hindlimb laminitis and is rare. Horses often tread and exhibit an unusual hindlimb gait (shortened caudal phase of the stride) when moved at a walk in hand. Pain arising from the thoracolumbar region may also result in a camped under posture.

Soft Tissue Injuries Altering Hindlimb Posture

Upward fixation of the patella causes rigid extension of all hindlimb joints in a standing horse (Figure 5-18). Patellar dysfunction resulting in fixed extension of the stifle also causes extension of the tarsus and lower limb joints because of the hindlimb reciprocal apparatus. The horse may

Fig. 5-17 • A 2-year-old Belgian gelding with a fracture of the right femoral head and neck exhibits external rotation of the right hindlimb. Varus deformity of the left hindlimb also is visible.

maintain this posture during movement, or the posture may be intermittent and resolve when the horse is moved. Occasionally a horse with severe hindlimb lameness assumes a similar posture, apparently hanging the limb, but the limb is not locked in extension (Figure 5-19). Normal horses simply resting a hindlimb, or those with severe lameness, usually keep the sole facing the ground.

Foals with unilateral or bilateral lateral patellar luxation have an unusual crouched hindlimb posture similar to femoral nerve paresis. The foal may have difficulty in rising if the condition is bilateral and severe or long-standing.

Disruption of fibularis (peroneus) tertius allows the hock to extend abnormally during weight bearing. Foals occasionally stand excessively straight in the hock (extended) in the affected hindlimb. In foals the injury usually causes tearing at the origin of fibularis tertius from the distal aspect of the femur, but in adults injury may occur in the crus or at the distal aspect of the ligament as it courses over the hock. Swelling and excessive hock extension may occur with the latter injury (Figure 5-20). The diagnosis is confirmed by manipulation: the hock can be extended while the stifle is flexed.

Rupture of the gastrocnemius tendon, or severe injury at any level of the muscle-tendon unit, causes mild or severe hindlimb postural change. During weight bearing,

Fig. 5-18 • A horse with the classic posture seen with upward fixation of the patella. All joints are held in rigid extension, and the horse is forced to rest or bear weight on the dorsal aspect of the hoof wall.

the hock flexes excessively as the stifle is held in extension, so the point of the hock drops. This injury is called *disruption of the caudal component of the reciprocal apparatus*.^{8,9}

Peripheral Nerve Deficits (see Chapter 11)

Sciatic nerve damage is rare. It occurs in foals as a result of injections into the thigh or rump or may occur transiently after injection of local anesthetic solution caudal to the coxofemoral joint. Horses with sciatic nerve damage support weight but appear to be crouched behind, because innervation to the gastrocnemius, flexor, and extensor muscles causes the hock to drop and fetlock to knuckle forward. Careful observation of stifle action and the ability to support weight are useful for attempting to differentiate this deficit from femoral nerve paresis.

Horses with femoral nerve paresis also assume a crouched hindlimb posture but are unable to bear weight, and the stifle drops substantially (Figure 5-21). Because the reciprocal apparatus is intact, the inability to fix the stifle leads to hock flexion and knuckling (flexion) of the fetlock joint. If the condition is bilateral, the horse is unable to rise for more than a few seconds. Femoral nerve paresis may occur unilaterally or bilaterally after general anesthesia or may result from lower motor neuron disease or injury.

Solitary tibial nerve injury is rare. Fibular (peroneal) nerve injury usually is recognized after general anesthesia and causes characteristic knuckling of the fetlock joint. Tibial nerve injury is differentiated from sciatic injury by lack of involvement of the fibular nerve, and thus normal

Fig. 5-19 • Belgian gelding shown in Figure 5-17. This horse occasionally rested the left hindlimb in this extended position, similar to that of upward fixation of the patella. Most normal horses, or those with severe lameness, prefer to rest the limb with the sole facing the ground.

positioning of the hock, and from femoral nerve injury, because horses are able to support weight and fix the stifle.

A rare polyneuropathy in Norwegian horses caused unilateral or bilateral knuckling of the hindlimbs, and in some horses paraplegia occurred as a result of peripheral injury of the sciatic nerves.¹⁰ A common epidemiological factor in all horses was the feeding of big bale silage or hay of poor quality.¹⁰ I have seen similar clinical signs in a Warmblood gelding, which developed acute, severe, bilateral hindlimb knuckling (at the fetlock) that resolved completely several days after onset. The cause in this horse was not determined.

Other Unusual Leg Positions

Horses with severe lameness occasionally rest a hindlimb back, forward, or abducted. Often these positions also are maintained during movement. Horses with caudal thigh or pelvic pain prefer to keep the affected hindlimb back, behind the unaffected limb. Horses with shivers may stand with the limb slightly abducted and more caudal than expected, with elevation of the tail head (see Chapter 48).

Stance in Horses with Pelvic Fractures and Conditions Affecting the Coxofemoral Region

Horses with pelvic fractures, in particular those involving the acetabulum, or other severe conditions involving the coxofemoral joint often stand with the limb slightly

Fig. 5-20 • This Thoroughbred racehorse with fibularis tertius injury has swelling over the dorsal aspect of the hock (*arrow*) and straight-in-the-hock conformation.

forward and often are reluctant to place the limb behind the unaffected limb, thus reducing the caudal phase of the stride at the walk. In addition, horses will often stand with the limb externally rotated, and in the rare instance there is coxofemoral luxation, the point of the hock of the affected limb will be slightly proximal to the contralateral point of the hock (see Figure 5-17). I find it interesting that children with infectious arthritis of the coxofemoral joint will often hold the affected hip in flexion, abduction, and external rotation,^{14,12} remarkably similar to those clinical

Fig. 5-21 • Thoroughbred with transient, postanesthesia, unilateral (left hindlimb) femoral nerve paresis. The crouched posture of the left hindlimb includes flexion (knuckling) of the fetlock joint.

signs seen in the horse. Horses with pain in the medial thigh and groin area stand with the limb abducted and may travel in this manner. Adductor muscle damage, medial thigh abscessation, and scirrhous cord or other inguinal problems also cause this posture.

Chapter 6

Palpation

Mike W. Ross

Palpation is an important part of a lameness examination. In some sports horses, it becomes more important because, for example, suspensory desmitis often is not associated with overt lameness but may compromise performance.

The veterinarian must develop a system to evaluate comprehensively all parts of the musculoskeletal system. I palpate in order each forelimb, the neck, the back, the pelvic regions, and then the hindlimbs. Each limb should be assessed when bearing weight and then again with the limb elevated from the ground. Deep palpation is used to describe direct, digital palpation, with the limb in an elevated position.

If time permits, palpation should be completed *before* the horse is moved, because if the lame limb is identified first, the other limbs may be overlooked and compensatory problems may be missed. For example, in a Thoroughbred (TB) racehorse, superficial digital flexor (SDF) tendonitis is

a common compensatory problem caused by contralateral forelimb lameness resulting in overload. If a lame horse with left forelimb lameness is first examined while the horse is moving, and subsequent palpation of the limb reveals signs of possible fetlock osteoarthritis, mild swelling of the right forelimb SDF tendon (SDFT) may be missed. Comprehensive palpation may allow the clinician to make predictions about lameness, to “read” the horse. Palpation before exercise also facilitates identification of localized heat or swelling, because limb temperature increases with exercise, and swelling often decreases.

THE ART OF PALPATION

The veterinarian should palpate and manipulate every possible anatomical structure, using the fingers and hands to push, prod, and feel. Interpretation of an abnormal response requires appreciation of the normal response. There are nerves beneath or adjacent to many structures, and direct pressure may elicit an apparently positive response. Such false-positive responses often occur during palpation of the origin of the suspensory ligament (SL) or the proximal sesamoid bones (PSBs). Care should be taken to apply pressure only in the desired location. During palpation of the PSBs, distal aspect of the SL, and digital flexor tendons, it is easy to apply pressure over the dorsal aspect of the third metacarpal bone (McIII), and a painful response may actually reflect sore shins.

The clinician should look for signs of inflammation: heat, pain, redness, swelling, and loss of function. One side of the horse should be compared with the other, but it should be remembered that both sides may be abnormal. Heat is one of the earliest clinical signs to develop with articular or nonarticular problems and may be the only sign. Subchondral remodeling and sclerosis of the third carpal bone often cause lameness in young racehorses, but effusion of the middle carpal joint and a positive response to flexion are found inconsistently. Usually prominent heat is detectable on the dorsal aspect of the carpus. It is important to recognize normality. A normal horse may have disparity in foot temperature. Horses often have two or three cold feet, but the other foot or feet feel warm. A few hours later, feet that previously were cool may feel warm. Foot temperature often reflects variations in ambient temperature, and care must be taken not to overinterpret this normal finding. In general, palpation is done with the palm side of the hand, although the back of the hand may be more sensitive to detection of warmth.

The veterinarian should assess the quality or strength of the digital pulse. In a normal horse, reliable detection of a digital pulse may be difficult, especially in cold weather or in horses with a thick hair coat. *Increased or elevated digital pulse* refers to the detection of increased strength (amplitude) or the bounding nature of the digital pulse. Inflammatory conditions in the foot or pastern region, such as abscesses, laminitis, hoof avulsions, or cracks, are the most common causes of increased digital pulse amplitude. Complete absence of hindlimb digital pulse may occur with aortoiliac thromboembolism or other vascular problems, but care should be taken when interpreting weak or near absent hindlimb digital pulses, because hindlimb digital pulses can be difficult to feel in normal horses.

Redness is difficult to perceive in the horse because of skin pigmentation, but in the foot, solar bruising or redness at the coronary band can be observed, especially in horses with nonpigmented feet. *Swelling* is often detected by observation, but subtle enlargement of structures such as the SL, or presence of effusion may be determined only by careful palpation.

Loss of function of tissues and regions can be assessed during palpation. Manipulation, flexion, and extension of the joints or soft tissues provide a better idea of function or loss of function. Static flexion and extension determine the range of motion of a joint and the horse's response to the procedure. Chronic osteoarthritis of the fetlock or carpal joints often results in reduced range of flexion. However, many horses in work but without lameness resent hard flexion of the lower limbs. Good correlation between a reduction in fetlock flexion range, lameness, and severity of osteoarthritis was found in TB racehorses.¹ A reduction in fetlock flexibility in young Warmbloods may be a predictor of future lameness.² The response to rotation of joints also should be assessed.

Crepitus, the grating or crackling sound made by bone rubbing on bone, is an unusual and ominous clinical sign usually determined by palpation, although in horses with prominent osteoarthritis or fractures a grating sound may be heard. A stethoscope may be useful for detection of subtle crepitus.

Other factors may confound the results of palpation. Clipped areas usually are warmer than an adjacent area with normal hair length. Blistering or freeze firing can cause localized pain for weeks after application, even if lameness has resolved. Any type of skin lesion, such as those found in horses with scratches or boot rubs, can cause extreme soreness to palpation but no signs of lameness. Some individual horses are more sensitive to palpation than others, and interpretation of apparent pain can be frustrating.

PALPATION OF THE FORELIMB

Foot

The importance of the foot cannot be overemphasized, and it is for this reason that palpation of the forelimb begins here. The feet are included in evaluation of conformation, symmetry, and posture. Detailed static examination (examination at rest) of the foot must always be supplemented with, and correlated to, dynamic observations of foot flight and foot striking patterns. Some horses continually attempt to pick up the limb as the clinician tries to evaluate it with the horse in the standing position; it may be necessary to stroke the contralateral limb to divert attention. A hoof pick, wire brush, hoof knife, shoe-removing equipment, and hoof testers are required (Figure 6-1). The sole and frog and wall of the foot should be cleaned thoroughly. Removal of the shoe at this stage in the examination usually is indicated only if a subsolar abscess is suspected. The veterinarian should take care to preserve the hoof wall, and if it is cracked, protect it with tape.

Foot and hoof balance are assessed by evaluating toe and heel length, hoof capsule conformation, condition and integrity, type of shoe and shoe position relative to the hoof capsule, hoof and pastern angle (axis), medial-to-lateral hoof balance, coronary band conformation, and

Fig. 6-1 • Instruments needed to examine the hoof, remove a shoe without tearing the hoof wall, and prepare the hoof for radiographic examination. Shown are apron, rasp, shoe pullers, nail pullers, clinch tool, hoof knife, hammer and hoof pick, and wire brush.

distal interphalangeal (coffin) joint capsule distention and response to hoof testers. The coronary band should normally be parallel to the ground surface. Deviation from parallel often indicates mediolateral foot imbalance ([Figure 6-2](#)). Medial and lateral wall lengths should be assessed while the horse is standing and again with the limb off the ground, with the foot viewed from palmar to dorsal along the solar aspect. The limb is lifted and held in neutral position so the solar surface is perpendicular to the ground. Sheared and underrun heels are commonly associated with lameness ([Figure 6-3](#)). Deformation of the hoof capsule is not necessarily a cause of lameness. Many horses with proximal displacement of the medial heel bulb have level foot strikes and otherwise balanced feet. Toe and heel length should be assessed, and the hoof-pastern axis should be determined. The angle of the hoof and pastern should be equal to allow equal loading of all portions of the foot. Forelimb hoof-pastern angles normally range from 48 to 55 degrees, but the absolute angle should not be overemphasized. A straight (parallel) pastern-foot axis is more important. A long-toe, underrun-heel foot conformation causes a broken foot axis and predisposes to palmar foot pain ([Figure 6-4](#)).

The conformation, condition, and integrity of the hoof capsule should be assessed. It is easy to miss hoof wall defects on the medial aspect. Small quarter or heel cracks and defects at the coronary band should not be overlooked. The clinician should evaluate the solar surface, bars, and frog. Thrush, although a reflection of poor management, rarely causes lameness.

The shoe type, shoe wear patterns, and the shoe size relative to the foot need to be assessed. The clinician should note the presence of pads or additions to the shoe, such as toe grabs, borium, and heel caulks. There is an association between toe grabs and suspensory apparatus failure in TB racehorses.³ Low heel angle also has been associated with injury.⁴ Shoe wear is important, because it reflects how the horse has been moving over the last several weeks. The clinician should note the breakover point and whether one branch of the shoe is worn more than the other. Shoe size should be assessed relative to foot size and the fit of the

Fig. 6-2 • The coronary band is uneven compared with the ground in this trotter's unbalanced left forelimb hoof. The medial wall (*right*) appears to be shorter than the lateral wall. A toe weight and bariun point are also shown.

shoe. A shoe that is too small or set too close to the frog may predispose to lameness.

Careful palpation of the coronary band in the standing and non-weight-bearing position is critical in detecting foot soreness ([Figure 6-5](#)). In horses with sore feet, heat and pain often are detected on the sore side of the foot, and a prominent digital pulse usually is present. Effusion of the distal interphalangeal joint capsule accompanies many abnormalities of the foot, from early synovitis to chronic osteoarthritis of the distal interphalangeal joint, and those with non-specific foot soreness. The clinician places one finger lateral to, and another medial to, the common digital extensor tendon and gently pushes in on the joint capsule, first laterally and then medially. *Ballottement* is a useful technique to detect effusion in many synovial structures: with effusion, pushing in on the capsule on one side of the tendon causes elevation of the capsule on the other side. The region of the collateral ligaments of the distal interphalangeal joint should be assessed carefully; focal heat or mild swelling may signify acute injury.

The clinician should palpate the cartilages of the foot, either with the horse standing or with the limb elevated. *Sidebone*, mineralization of the cartilages of the foot, rarely causes lameness. The cartilages of the foot normally are pliable and readily compressed axially. Fracture at the

Fig. 6-3 • Elevated foot viewed from the palmar aspects shows that the hairline at the medial bulb of heel (on the right) is displaced proximally compared with the lateral heel bulb. The medial wall is longer. Note also the prominent cleft between the heel bulbs. These features are typical of a sheared heel.

Fig. 6-4 • This trotter has long toe, underrun heel hoof conformation, and broken hoof-pastern axis.

Fig. 6-5 • Palpation of the coronary band should include assessing the dorsal joint pouch of the distal interphalangeal joint. In this horse, distal interphalangeal effusion and fibrosis appear as a bulge just proximal to the coronary band, dorsally.

Fig. 6-6 • A variety of hoof testers are available for lameness examinations. I prefer hoof testers that are easily adjusted and used in one hand (two pairs on the right). Large hoof testers (*left*) can be applied only with two hands, and small hoof testers (*bottom*) are inappropriate for medium to large hooves.

attachment of the cartilage of the foot to the distal phalanx is an occasional cause of lameness, and compression of the heel with hoof testers may elicit pain in some horses. Horses with sidebone often have medial-to-lateral hoof imbalance.

Hoof Tester Examination

“... I feel naked going into a stall without my hoof testers!”⁵ Hoof testers are essential for evaluation of the foot and are a basic requirement for all lameness examinations. Many types of hoof testers are available ([Figure 6-6](#)), but I favor

Fig. 6-7 • Hoof testers should be applied from the sole to the wall, from heel to toe, and to both sides of the hoof.

one that is adjustable and can be applied with one hand. A proper evaluation of the foot with hoof testers cannot be done with a pad in place, although useful information can be acquired. The instrument can be applied with or without a shoe in place. The amount of force to apply varies from horse to horse and by region of the hoof, and both false-positive and false-negative responses occur. More force is required when the instrument is used across the heel than when used from sole to quarter. The foot should be held between the clinician's legs in a relaxed manner. The clinician must be able to feel the horse react to subtle pressure, and if the limb is held too tightly or the horse is not calm during the examination, it is difficult to feel a response. The veterinarian should be careful not to place the outside jaw of the instrument too close to the coronary band, because this may cause a false-positive result. Sole sensitivity is assessed by applying the instrument to three to five sites from heel to toe, on both the medial and lateral aspects of the foot, starting from the angle of the sole (seat of the corn) and proceeding dorsally (Figure 6-7). The responses should be compared. If the sole is readily compressible, pain from bruising, a subsolar abscess, laminitis, fracture of the distal phalanx, and other injuries may be elicited, but in horses with hard horn the response may be negative. To evaluate sensitivity of the frog and underlying deeper structures, the hoof testers should be applied from the lateral aspect of the frog to the medial wall, and from the medial aspect of the frog to the lateral wall, each in the palmar, midportion, and dorsal aspects of the frog (Figure 6-8). Pain over the middle third of the frog has been attributed to navicular disease or navicular syndrome, but the specificity of this association is questionable and there are many false-negative responses. Horses with generalized foot soreness or any other cause of palmar foot pain may respond positively or not at all. Only 19 of 42 horses with navicular region pain responded positively to hoof tester examination in the middle third of the frog, with 50% specificity, 50% positive predictive value, and 48% accuracy.⁶ Horses with palmar foot pain caused by other conditions were as likely to respond to the test, a finding that obviously prompts questioning of the value of hoof tester

Fig. 6-8 • Hoof testers applied from the middle of the frog to the contra-lateral hoof wall put pressure on the navicular region. Horses with many abnormal conditions of the hoof may manifest a positive response.

examination.⁶ It is difficult if not impossible to create adequate pressure to cause pain in large breed horses or if the horn is hard. Application of a poultice or soaking the foot may be necessary to soften a hard foot, and reexamination after several days may be rewarding. Hoof tester application to the small feet of foals or ponies may elicit a false-positive response, and hoof tester size or amount of compression may require adjustment.

Application of hoof testers across the heel may cause pain in horses with palmar foot pain but is not specific (Figure 6-9). Application of the hoof tester to the area of the sole adjacent to each nail, nail hole, or defect in the sole or white line is useful to detect a subsolar abscess or a close nail (Figure 6-10). Areas of pain can be gently explored with a hoof knife, but unless clearly indicated, the veterinarian should refrain from digging too deeply. The hoof tester can then be used as a hammer to percuss each nail in the shoe and the frog and toe regions.

After completing the hoof tester examination, the clinician should reassess the digital pulses. In horses with foot pain the digital pulse may now be bounding. Horses that have recently been shod or trimmed or have raced or performed recently, especially on hard surfaces, may have mild elevations in digital pulse amplitude and may show hoof tester sensitivity normally. Pain causing lameness may not be in the foot.

Wedge Test and Other Forms of Static Manipulation

The wedge test is used most commonly as a dynamic procedure to induce lameness during the movement phase of the examination, but can be used to assess the static response of a horse to dramatic changes in dorsal-to-palmar or medial-to-lateral hoof angles (see Chapter 8, Figure 8-12). A digital extension device, with which the author gauged static painful responses to changes in hoof

Fig. 6-9 • Adjustable hoof testers are easily placed across the heel. I prefer to apply hoof testers in this manner to assess horses for palmar foot pain during static examination and as a provocative test for lameness.

angle to make shoeing recommendations, was recently described.⁷

Pastern

The proximal interphalangeal (pastern) joint capsule is assessed by ballottement, although severe effusion must be

Fig. 6-11 • Palpation of oblique distal sesamoidean ligaments.

present for fluid distention to be perceived. Bony swelling associated with this joint, proximal or high ringbone, is a classic cause of lameness yet an unusual clinical finding. Osteoarthritis of the proximal interphalangeal joint is a common diagnosis, but one made by a combination of clinical findings, diagnostic analgesia, radiography, and sometimes scintigraphy. The distal extent of the digital flexor tendon sheath (DFTS), deep digital flexor tendon (DDFT), and distal sesamoidean ligaments are palpated. Deep pain associated with the origin and insertion of the distal sesamoidean ligaments is assessed by palpation with the limb in flexion (Figure 6-11). In some horses with lesions of the DDFT within the hoof capsule a positive response to compression of the palmar pastern region is present, but this finding is inconsistent and many false-negative responses occur. The oblique sesamoidean ligaments are difficult to differentiate from the branches of the SDFT, but injury of the SDFT is more common. Distal sesamoidean desmitis or chronic suspensory desmitis may result in subluxation of the proximal interphalangeal joint (Figure 6-12). Swelling should prompt ultrasonographic examination if relevance has been confirmed using diagnostic analgesia. The proximal interphalangeal joint is manipulated in a medial-to-lateral direction to assess pain and collateral ligament integrity and is flexed independently of the fetlock joint. The proximal, dorsal aspect of the proximal phalanx is palpated (Figure 6-13). Horses with short, midsagittal fractures or dorsal frontal fractures of the proximal phalanx or proliferation at the attachment of the common digital extensor tendon may show pain. Enthesophyte formation at the common digital extensor tendon attachment, seen most commonly in older ex-racehorses with chronic osteoarthritis of the fetlock joint, results in prominent bony and soft tissue swelling and pain on palpation.

Fetlock

The clinician palpates the joint capsule of the metacarpophalangeal (fetlock) joint with the limb bearing weight,

Fig. 6-12 • Subluxation and osteoarthritis of the left front proximal interphalangeal joint resulted from primary suspensory desmitis.

Fig. 6-14 • Digital pulse quality can be assessed easily at the level of the proximal sesamoid bones.

Fig. 6-13 • Proliferative changes at the common digital extensor attachment or pain from midsagittal fracture of the proximal phalanx should be palpated along the dorsal, proximal aspect of the proximal phalanx.

keeping in mind that pain associated with the joint can be present without localizing clinical signs. The dorsal aspect is palpated using ballottement on either side of the common digital extensor tendon. The clinician should determine whether localized heat is present. *Osselets* is a North American term used to describe early osteoarthritis of the metacarpophalangeal joint in young racehorses, with firm bony

and soft tissue swelling on the dorsal, medial aspect of the proximal phalanx, and the distal aspect of the McIII, caused by traumatic capsulitis and early enthesophyte formation. Occasionally in horses with prominent effusion of the metacarpophalangeal joint, a soft tissue swelling can be palpated in the proximal, dorsal aspect of the joint from excessive proliferation of the dorsal synovial pads, called *proliferative* or *villonodular synovitis*. The palmar pouch of the metacarpophalangeal joint is palpated dorsal to the SL branches, both medially and laterally. Mild effusion may be present without associated lameness, especially in older performance horses. The PSBs are palpated and assessed for mild swelling and heat, clinical signs of sesamoiditis, or SL avulsion injury. The digital pulse amplitude is reassessed by placing fingers both medially and laterally, abaxial to both PSBs (Figure 6-14).

The DFTS extends from the distal metacarpal region to the distal palmar aspect of the pastern. Usually no palpable fluid is found. Effusion of the DFTS (tenosynovitis) causes swelling in the palmar fetlock region that must be differentiated from effusion of the metacarpophalangeal joint. Tenosynovitis causes swelling *palmar* to the branches of the SL, medially and laterally. Fluid can be compressed from medial to lateral. With severe effusion, distention is found in the palmar aspect of the pastern, but there may be distention proximal to the palmar annular ligament without obvious distention distally. *Wind puffs* or *windgalls* describe incidental fluid distention of the DFTS, commonly seen in older performance horses unassociated with lameness. Tenosynovitis can cause lameness, but additional diagnostic techniques are required to confirm the diagnosis.

The limb is elevated to assess range of joint motion and the horse's response to flexion. Normally the fetlock can be flexed to 90 degrees (the angle between the proximal phalanx and the McIII) or slightly more. A reduction in fetlock flexion range is indicative of chronic fibrosis but is

not necessarily a cause for concern. A pronounced response to static flexion is noteworthy, although many horses resent static flexion but do not show a positive response to dynamic flexion (lower limb or fetlock flexion tests; see Chapter 8). Horses with clinically relevant tenosynovitis usually strongly resent fetlock flexion. With the limb in flexion, the clinician palpates the PSBs and the branches of the SL, avoiding compression of the palmar digital nerves.

Metacarpal Region

The clinician should assess the dorsal aspect of the McIII for heat and swelling. This is a common area for traumatic injury (barked shins) or stress-related bone injury (bucked shin syndrome). Many ex-racehorses have incidental, prominent, chronic, and nonpainful swelling of the McIII caused by extensive modeling and remodeling of the dorsal cortex while in race training. Racehorses currently in training may have heat and pain on deep palpation (performed with the limb elevated), but prominent swelling may be lacking. Any combination of palpation findings is possible in horses with stress-related bone injury of the McIII. It is difficult to apply deep pressure to the dorsal aspect of the McIII without concomitant pressure to the palmar soft tissue structures or PSBs, so the responses should be assessed carefully.

The entire length (abaxial surface) of the second and fourth metacarpal bones (McII/IV) should be palpated with the horse in the standing position to detect exostoses, callus, or fractures. Swelling of the SL branches or body may make this difficult. Palpation of the McII and the McIV should be repeated with the limb elevated, because the axial aspect of these bones is impossible to assess in the weight-bearing position. Splint exostoses are common, particularly in young horses. Therefore the presence of even large bony swellings is not unusual. Exostoses detected axially, possibly impinging on the SL or causing adhesions to the SL (or so-called “blind splints”) should be carefully noted. Both false-positive and false-negative results can occur when palpating a splint exostosis and results of palpation and compression should be confirmed using perineural analgesia. Pain from even small exostoses of the McII and the McIV usually is more accurately assessed immediately after training or racing, because pain and lameness resulting from these swellings can be subtle and transient. The clinician should carefully palpate the SL branches. Differentiation of branch or SL body injuries is important: the latter injuries usually are more serious and have a worse prognosis.

The medial and lateral palmar digital vein, artery, and nerve, in dorsal-to-palmar orientation, respectively, are located between the SL and DDFT. The accessory ligament (distal or inferior check ligament) of the DDFT (ALDDFT) normally is difficult to palpate and even when enlarged cannot easily be differentiated from the DDFT, but injuries of the ALDDFT are more common. All soft tissue structures should be palpated carefully, using digital compression, with the limb elevated (Figure 6-15). Acute or chronic swelling should be assessed, as should the horse's response to deep palpation. Obvious swelling and pain indicate the presence of tendonitis or desmitis. In some horses with acute severe tendonitis or desmitis the structure feels “mushy” or soft in the area of fiber damage. This finding, especially in horses with fetlock drop, indicates near rupture of the structure. There are many false-positive and

Fig. 6-15 • The soft tissue structures in the palmar metacarpal region should be carefully palpated with the horse in standing and flexed (shown) positions for heat, pain on compression, and swelling. Most ridden horses have mild pain, but in racehorses a painful response is an early sign of tendonitis or desmitis.

even false-negative responses to palpation of the digital flexor tendons and SL. In most ridden performance horses a mild painful response (false-positive) to deep palpation of the SL is normal. However, in racehorses, false-positive responses are less common, and a painful response to deep palpation may indicate the presence of early desmitis or tendonitis. In many horses with foot lameness, secondary, mild suspensory desmitis is common. There is a painful response to palpation of the body and origin of the SL. It may be difficult to decide whether this is a true or false-positive response, a determination that often is made in hindsight after the lameness examination is finished. False-positive and false-negative responses to palpation of the proximal palmar metacarpal region also occur. This is a common site of lameness and should be examined carefully. Palpation must be done with the limb in flexion, and the presence of swelling and pain must be carefully interpreted (Figure 6-16). Horses with acute injuries, such as proximal suspensory desmitis (PSD), avulsion or longitudinal fracture of the McIII, and stress reaction of the McIII at the origin of the SL, may have swelling and pain. Deep palpation may create pressure on the palmar metacarpal nerves resulting in a false-positive pain response, and many horses with PSD have no localizing signs. The most proximal aspect of the SDFT is difficult to palpate with the limb in a flexed position, and mild swelling from tendonitis can easily be missed. When the limb is weight bearing, the expected convex profile associated with SDF tendonitis in the mid-to-distal regions of the metacarpal region is usually not seen because of pressure from the overlying metacarpal fascia. Careful palpation of the proximal aspect of the SDFT, particularly in horses that negotiate fences or in ponies, is necessary to avoid missing subtle lesions. This injury is particularly hard to recognize in horses or ponies with long hair coats.

The proximal dorsal aspect of the McIII should be palpated in a flexed position (Figure 6-17). Occasionally, dorsomedial articular fracture of the McIII results in a subtle

Fig. 6-16 • Palpation of the proximopalmar metacarpal region is essential in diagnosing proximal suspensory desmitis and other conditions of the suspensory origin and differentiating lameness in the region from carpal lameness. (Courtesy Ross Rich, Cave Creek, Arizona.)

Fig. 6-17 • Careful palpation of the proximal, dorsal metacarpal region identifies pain associated with dorsomedial articular fracture or other fractures of the proximal aspect of the third metacarpal bone. (Courtesy Ross Rich, Cave Creek, Arizona.)

painful swelling. Swelling (effusion) of the carpal sheath may be detected in the proximal medial metacarpal region, but large veins (medial palmar, accessory cephalic, and cephalic veins) may interfere with accurate palpation. With mild tenosynovitis, effusion may be difficult to discern.

Fig. 6-18 • Carpal tenosynovitis must be differentiated from effusion of the antebrachiocarpal joint. This horse with severe superficial digital flexor tendonitis has moderate distention of the carpal sheath (arrow) in the caudal, distal aspect of the antebrachium and medially in the proximal metacarpal region (not shown).

Carpus

Detection of warmth on the dorsal aspect of the carpus is a reliable indicator of underlying inflammation. Obviously, one side should be compared with the other, but bilateral conditions exist commonly. Previous application of counterirritants interferes with the reliable detection of warmth. Carpal joint lameness without obvious signs of synovitis is common, but if present, effusion is easily palpated using ballottement. With the horse in the standing position, a finger is placed dorsolaterally between the extensor carpi radialis and common digital extensor tendons, and another finger is placed just medial to the extensor carpi radialis tendon. These openings are used for palpation and arthrocentesis of both the middle carpal and the antebrachiocarpal joints. The middle carpal and the carpometacarpal joints always communicate, but a small synovial compartment and dense overlying soft tissue structures limit palpation of the carpometacarpal joint. Both the middle carpal and the antebrachiocarpal joints have a palmarolateral pouch that may be distended if effusion is severe. If swelling is detected just caudal to the radius, it is necessary to differentiate distention of the palmarolateral pouch of the antebrachiocarpal joint from the carpal sheath (Figure 6-18). In horses with antebrachiocarpal joint effusion the dorsal outpouchings also should be prominent, whereas in those with carpal sheath effusion, fluid distention is restricted to the palmar aspect and also detected medially, both proximal and distal to the accessory carpal bone.

Tenosynovitis of the extensor carpi radialis, common digital extensor, or lateral digital extensor sheaths results in vertically oriented swellings that traverse the carpal joints, may extend proximal or distal to the carpus, and usually are multilobed, being divided by bands of extensor retinaculum located dorsally and laterally.

Normally the carpus can easily be flexed completely, so that the palmar metacarpal region and bulbs of the heel touch the caudal aspect of the antebrachium. Reduced flexion may be caused by pain, with or without chronic fibrosis, associated with osteoarthritis. Pain during carpal flexion is a reliable indicator of carpal region pain but does not indicate the cause. The carpal sheath is compressed and the extensor tendons are stretched during this maneuver, and conditions involving these structures and the accessory carpal bone can cause pain during flexion. The elbow joint is flexed simultaneously; therefore a positive response to carpal flexion can rarely result from elbow pain. The examiner should palpate the dorsal surfaces of the carpal bones with the limb in partial flexion (Figure 6-19). Many pathological conditions associated with the carpus are manifested dorsally, and pain associated with osteochondral fragmentation, slab fractures or other severe injuries, or osteoarthritis can be assessed with the limb in this position. Focal pain can be identified, and loose fragments associated with the third carpal bone or distal lateral radius occasionally can be identified.

Antebrachium (Forearm)

Digital palpation of the forearm usually is performed with the limb bearing weight. The examiner should look primarily for muscle atrophy, wounds, or mild swelling associated with the radius. Small wounds in the antebrachium may look innocuous, but inappropriately severe lameness and pain on palpation may reflect a spiral radial fracture. The examiner should pay particular attention to the medial aspect of the limb; this area is easily overlooked when palpating from the lateral side. Distally, fluid distention of the carpal sheath or acute swelling associated with injury of the accessory ligament (proximal or superior check ligament) of the SDFT, or the flexor muscles and tendons can occur. The amount of muscle in the extensors and flexors should be compared with that in the contralateral limb, because subtle atrophy may be missed during observation.

Elbow

Frank swelling and prominent lameness accompany many injuries of the elbow region, but other problems of the elbow joint are discovered only after diagnostic analgesia has localized pain to this area or by use of advanced imaging modalities. It is nearly impossible to use diagnostic analgesic techniques to abolish pain in the distal aspect of the humerus and proximal aspects of the radius and ulna; therefore advanced imaging techniques are often required to identify problems in these structures. The clinician should palpate the olecranon process and the lateral and medial collateral ligaments with the limb bearing weight. Effusion is difficult to detect, but excess fluid occasionally can be found using ballottement, by placing fingers both cranial and caudal to the lateral collateral ligament. The elbow is flexed by pulling the distal limb in a cranial and proximal direction and then extended by

Fig. 6-19 • Careful palpation of the dorsal aspect of each carpal bone can be done with one hand (**A**) or by placing the distal limb between the clinician's legs and using both hands (**B**). A pain response indicates an osteochondral fragment or an osteophyte. Occasionally a loose osteochondral fragment can be palpated.

pulling the lower limb in a caudal direction. The shoulder joint is undergoing the opposite reaction during this manipulation, and pain associated with that joint or the bicipital bursa can cause a positive response during elbow manipulation.

Brachium (Arm) and Shoulder

The shoulder and intertubercular (bicipital) bursa are regularly blamed as the cause of lameness yet are seldom involved. Normal horses may resent palpation of this area. Pain in the muscles surrounding the shoulder joint may develop *secondary* to primary lower limb lameness. In Standardbred (STB) racehorses with carpal lameness, secondary pain often is detected when the bicipital bursa is palpated. A rare cause of lameness is infection as a result of a previous deep injection of the “shoulder bursae,” and horses may have only subtle pain on palpation and manipulation of the shoulder region. Infectious bicipital bursitis generally causes severe lameness, a marked shortened cranial phase of the stride, and a marked painful response to shoulder joint flexion.

Palpation of the arm is limited because overlying muscles obscure much of the humerus. Horses with displaced humeral fractures usually are unwilling to bear weight and have severe soft tissue swelling. Those with humeral stress fractures usually have no localizing signs except a positive response to upper limb manipulation. A normal intertubercular bursa is not palpable. Horses with bicipital bursitis usually resent direct compression of the greater tubercle of the humerus, and fluid distention may be palpable, but ballottement is usually limited. Effusion of the scapulohumeral (shoulder) joint is palpable only if severe and even then is easily overlooked.

Upper limb manipulation, including static flexion and extension to assess the range of motion of the shoulder and elbow joints and the presence of a painful response, should always be performed. This can be done during palpation of the elbow or later when the clinician finishes the shoulder region. Most horses with shoulder joint lameness or bicipital bursitis show a painful response when the limb is pulled backward (shoulder flexion, elbow extension), whereas those with elbow lameness may show a painful response when the limb is pulled forward (shoulder extension, elbow flexion).

The examiner should palpate the scapular area and move the mane if necessary. Atrophy of the infraspinatus and supraspinatus muscles may indicate suprascapular nerve or brachial plexus injury (Figure 6-20). Muscle atrophy of these and other forelimb muscles can be caused by other neurogenic causes or by disuse. Upper limb palpation often is used to confirm those findings recognized during observation of the horse. Scapular height is compared manually. Although rare, damage to the innervation of the serratus ventralis muscle or direct trauma to the muscle itself allows abnormal elevation of the injured side when the horse is standing or during movement. Pectoral muscle atrophy can easily be missed during observation, and the pectoral region should be palpated to assess pectoral muscle mass and identify swellings or wounds that may cause lameness.

PALPATION OF THE CERVICAL AND THORACOLUMBAR SPINE

Cervical Spine (Neck)

Palpation of the neck is limited. I usually palpate the brachiocephalicus muscle after shoulder palpation and manipulation, a procedure thought to have predictive but

Fig. 6-20 • This horse shows atrophy of the supraspinatus and infraspinatus muscles with concomitant lateral subluxation of the left shoulder joint.

nonspecific value in horses with forelimb lameness.⁸ The muscle is squeezed just cranial to the shoulder joint; most horses flinch, but some horses with ipsilateral forelimb lameness show a marked pain response. The examiner should palpate both sides of the neck, noting any swelling or muscle atrophy. Cervical abscessation can cause signs of neck pain and forelimb lameness. Muscle atrophy may indicate long-standing cervical pain or ipsilateral forelimb lameness. Muscle development of the neck may be asymmetrical, especially if viewed from above (the perspective of a rider).² Palpation of the poll region is important because undue soreness cranial to the wings of the atlas may be associated with poor performance.² The head should be moved from side to side to evaluate the horse's willingness to move the neck. One hand is placed on the midcervical region to use as a fulcrum, and the other hand is used to bend the head and neck toward the examiner. Food also can be used to entice the horse to move the head and neck from side to side. Normally a horse can reach around to the girth region on either side to ingest food, and reluctance to do so may indicate neck pain. This procedure may more closely mimic the horse's natural head and neck movement than using a hand in the midcervical area as a fulcrum. A more comprehensive examination, including neurological or chiropractic evaluations, may be necessary after completion of the lameness examination.

Up-and-down movement of the head also should be assessed. Although usually not a part of a routine lameness examination, evaluation of the temporomandibular joints and the mouth may be necessary in horses with poor performance.²

Thoracolumbar Spine (Back)

Additional detailed palpation of the back and pelvis may be necessary once the lameness examination has been completed. Chiropractic manipulation and assessment of acupuncture points may be useful but usually are reserved for specific horses or when history and clinical signs warrant such an examination and if the clinician is qualified to complete it. The cranial thoracic spine has already been briefly evaluated during examination of the shoulder for scapular symmetry. The withers should be examined closely for conformational abnormalities, such as those seen with fracture of the dorsal spinous processes or fistulous withers. The presence of sores may indicate an ill-fitting saddle and can cause performance-related problems. Using a hand on each side of the spine, the examiner should apply digital pressure to assess vertebral height, presence of pain, and muscle atrophy and to confirm symmetry (Figure 6-21). Many horses resent deep and aggressive palpation of the epaxial muscles, and the response of normal horses should be learned before a pathological response is presumed. Most horses readily become mildly lordotic (“scootch”) during deep digital palpation or when a blunt object, such as a pen, is used. Some clinicians prefer to use the ends of the fingers to “run” (apply digital pressure while moving the fingers caudally) the muscles from cranial to caudal, parallel to the spinal column. When this is continued along the gluteal muscles and rump, most normal horses become somewhat kyphotic and move forward slightly. Aggressive use of blunt or sharp objects to assess pain should be avoided. Some horses are stoic during palpation, and it may be impossible to stimulate them to extend and flex the thoracolumbar region without the use of a blunt instrument.² In these horses, firmly stroking the ventral abdomen may stimulate movement.² With one hand on the horse’s back during movement of the

Fig. 6-21 • Palpation of the thoracolumbar region should be performed in a quiet, careful manner. Many horses object to sudden or sharp stimuli applied to this region. Direct, even pressure is applied to the epaxial muscles (shown) and the summits of the dorsal spinous processes.

thoracolumbar spine, the clinician may be able to feel muscle “cracking” during the release of tension in the epaxial muscles.² The observation of muscle fasciculations during or after palpation usually indicates a degree of muscle pain. Failure to exhibit the normal lordotic or kyphotic responses, assumption of a guarded posture, and vocalization during the examination are further signs of back pain.

In many horses, back pain, and more specifically muscle pain, is secondary to hindlimb lameness, resulting from altered gait and posture. Any site of pain in the hindlimb may alter the gait to cause secondary upper limb or back muscle pain. The use of diagnostic analgesia to confirm the primary source of pain (in the hindlimb, or locally in the back) may be required to make the true diagnosis. Back pain often is complex and may be caused by many factors including ill-fitting saddles, poor riding, and other primary problems, such as overriding of dorsal spinous processes or other bony causes. The clinician should palpate carefully to detect localized swelling in the area of the saddle. Even small areas of hair loss without swelling may indicate a loose or ill-fitting saddle, abnormal movement of the saddle associated with hindlimb lameness, or a rider sitting crookedly.²

It is doubtful that muscular pain alone can cause unilateral hindlimb lameness. Back pain was induced in STB horses by injection of lactic acid into the left longissimus dorsi muscle and subsequently exercised and observed with high-speed cinematography.⁹ Frank lameness was not observed, but there was slight modification of left hindlimb stride and reduced performance. This supports the clinical observation that back pain usually is the result, not the cause, of obvious hindlimb lameness, although it may result in slight alterations in gait. Severe vertebral abnormalities or an abscess in the epaxial muscles may result in lameness or neurological dysfunction.

PALPATION OF THE LATERAL AND VENTRAL THORAX AND ABDOMEN

History or observation of lameness, performance, or behavioral abnormalities seen only when a horse is ridden or wearing tack should prompt examination of the thoracic region. Irritation from an ill-fitting girth or other sores or wounds can contribute to poor performance, and injury of the sternum or ribs can cause pain associated with saddling or being ridden. Traumatically induced hernias of the ventral abdomen can cause gait deficits or guarding of the abdomen.

PALPATION OF THE EXTERNAL GENITALIA

Testicular or inguinal pain should be considered as a cause of gait modification. Swelling, infection from previous castration, scirrhous cord, and mastitis can cause a change in gait. The veterinarian should determine the sex of the horse and the presence of one or both testicles.

PALPATION OF THE PELVIS

Palpation of the pelvis is performed to confirm previous observations. The horse should stand as squarely as possible. The clinician should palpate all bony protuberances,

Fig. 6-22 • Although the veterinarian must take care when standing behind any horse, this perspective is crucial in determining pelvic heights and widths. The height of each tuber coxae is compared in this photograph. Alternatively, an assistant on each side can be asked to point to a comparable location, or tape can be applied.

including the tubera coxae, tubera sacrale, and tubera ischii. The examiner stands behind the horse and palpates these paired protuberances simultaneously if it is safe to do so (Figure 6-22). Fracture of a tuber coxae or an ilial shaft may result in asymmetry, but if the ventral aspect of the tuber coxae is fractured, the height of the dorsal aspect may be equal to that of the contralateral side. The anatomy of the ventral aspect of the tuber coxae is distorted. Small muscle defects may be associated with fracture or enthesopathy of the tubera ischii, but even with a displaced fracture, palpation of this area may be unrewarding (Figure 6-23). If a pelvic injury or fracture is suspected, the clinician should gently rock (move) the horse from side to side. Subtle crepitus may be detected, but in many horses with pelvic fractures this is not apparent until days to weeks after injury and only during the initial portions of the examination before muscle guarding supervenes. The veterinarian should grasp the tail and elevate it. Many horses resist this, but in those with fractures of the base of the tail (most commonly from sitting in the starting gate or trailer), a true pain response is elicited. Subtle swelling also may be present. Lack of tail tone may indicate neurological disease.

Fig. 6-23 • The tubera ischii (shown) and third trochanters are palpated carefully. Enthesopathy or fracture causes lameness that is difficult to locate without careful palpation or scintigraphic examination. Occasionally, horses with small muscle defects located distal to the tubera ischii have chronic lameness from previous fracture. (Courtesy Carolyn Arnold, College Station, TX.)

Muscle pain and muscle atrophy should be assessed. The clinician carefully examines the gluteal musculature, the origin of the caudal thigh muscles, and the tensor fasciae latae (see Chapter 47 for further discussion of muscle assessment and palpation of the greater trochanter of the femur). Pain or soreness noted during palpation of the semimembranosus and semitendinosus muscles may be associated with injury of the ipsilateral tuber ischium.²

PALPATION OF THE PELVIS PER RECTUM

Rectal examination is not part of the routine lameness examination and should be reserved as a special examination procedure if pelvic fracture or aortoiliac thrombosis is suspected. With the wrist just inside the anus the veterinarian should palpate the medial and dorsal aspects of the acetabulum, comparing sides. In young horses, there is a membranous junction between pelvic bones in the center of the acetabulum; a defect and a small amount of motion normally can be felt. Just cranial to the acetabulum is the cranial aspect of the pubis (brim of the pelvis). With the arm at elbow depth the examiner should sweep the arm dorsally on each side to palpate the medial aspect of each ilium. The ventral aspect of the sacrum and sacroiliac region are compared. The clinician should compare the pulse quality between the right and left external iliac arteries and evaluate conformation and pulse quality of the terminal aorta and branches. Horses with aortoiliac thromboembolism have abnormal conformation and altered pulse quality. Crepitus may be felt more easily by gently rocking the horse from side to side, picking up one hindlimb, or walking the horse a short distance with the veterinarian's arm still within the rectum.

Asymmetry, swelling, actual fracture lines, fragments or callus, and crepitus are assessed. In horses with acute pelvic

fractures, crepitus, fracture fragments or lines, and callus usually are not detectable, but hematoma and soft tissue swelling usually can be felt. In horses with ilial wing or shaft fractures, large fracture hematomas often are present, but the absence of swelling does not preclude presence of ilial fractures. These horses are at risk to develop fatal hemorrhage. Edges of fracture fragments may be evident with comminuted or grossly displaced fractures. With chronic pelvic fractures, crepitus and callus may be more obvious.

PALPATION OF THE HINDLIMB

For safety reasons, I prefer to start proximally and work distally in a hindlimb, allowing the horse to become accustomed to palpation. Horses often object to palpation of the flank and stifle regions, and this should not be misinterpreted as a sign of pain. The clinician should grasp the tail and pull it gently toward himself or herself to keep the ipsilateral hindlimb bearing weight and reduce the chance of the horse kicking. It may be useful to pick up the ipsilateral forelimb. In the large majority of horses the entire limb can be safely examined while bearing weight, but pain in the lame limb or contralateral limb or the horse's behavior may make it difficult or impossible to pick up the limb. Reluctance to pick up the hindlimbs has been attributed to unilateral or bilateral sacroiliac pain.² Horses with shivers often are reluctant or anxious to pick up one or both hindlimbs. It may be necessary to spend a small amount of time coaxing the horse to elevate the hindlimb, at first just high enough to examine or pick out the hind foot and then progressing to full flexion. Although historically the hock and stifle joints have been regarded as the principal sources of pain causing hindlimb lameness, there are many other potential sites, and the metatarsal and fetlock regions in particular should be examined with care.

Thigh

The clinician should assess the thigh for swelling, muscle atrophy, or scarring. Horses with femoral fractures usually have obvious severe swelling, crepitus, and instability of the limb. The third trochanter of the femur is difficult to feel, and clinical abnormalities associated with enthesopathy of the insertion of the superficial gluteal muscle or a fracture usually are impossible to detect. Scarring associated with the semitendinosus, the semimembranosus, and rarely the biceps femoris can lead to mechanical gait deficits, known as *fibrotic myopathy*. The gastrocnemius muscle arises from the distal caudal aspect of the femur, and acute tearing of this muscle may cause swelling in the caudal stifle area. This is difficult to perceive, but severe muscle injury results in a marked postural change, which should provoke more careful assessment of this region.

Stifle

Palpation of the stifle is limited to the cranial, lateral, and medial aspects; unfortunately, the caudal and proximal aspects of the joint are inaccessible. Many horses, especially fillies, object to palpation of the stifle, a normal response often misinterpreted as a painful reaction.

The veterinarian should palpate the stifle with the limb bearing weight. The foot should be flat on the ground. This may be impossible if the horse has severe pain prohibiting complete assessment of the stifle. The limb should be in a

neutral and not in an abducted position and should be perpendicular to the spine or slightly ahead of the other hindlimb. If the limb is retracted, it is more difficult to palpate the patellar ligaments and joint outpouchings. The middle patellar ligament is identified and followed proximally to the distal aspect of the patella. The clinician should feel the femoropatellar joint capsule between either the middle and medial or the middle and lateral patellar ligaments and should determine the presence of effusion. In horses with osteochondritis dissecans (OCD), fluid distention can be pronounced. However, normal young horses (weanlings to early 2-year-olds) often have prominent bilateral fluid distention of the femoropatellar joint capsules.

The clinician should find the medial patellar ligament and follow it proximally and distally. At the proximal extent, the medial fibrocartilage of the patella can be felt medial to the medial trochlear ridge of the femur. It is this normal arrangement of the medial aspect of the patella and the medial trochlear ridge that allows the veterinarian to determine whether a horse has patellar luxation. The position of the patella is difficult to confirm if the horse is standing with the stifle flexed. True patellar luxation is rare. The examiner should determine if the medial patellar ligament is enlarged, which usually reflects previous desmotomy or dermoplasty. Usually a distinct depression is present between the medial patellar ligament and the medial collateral ligament, but effusion of the medial femorotibial (MFT) joint may result in a substantial "bulge" (Figure 6-24). This may be the only clinical sign indicative of MFT joint injury.

The lateral and middle patellar ligaments are palpated from their origin to insertion. Patellar desmitis is unusual but does occur; it usually involves the middle patellar ligament and may cause mild swelling. Previous injection with counterirritants causes firm, fibrous areas over the patellar ligaments, a common finding in racehorses. Gently rocking the horse from side to side to assess motion of the patella may give some indication of the potential for intermittent upward fixation of the patella (IUFP). In horses prone to IUFP, jerky rather than the normal smooth motion of the patella sometimes is detected.² The lateral femorotibial (LFT) joint capsule is accessed between the lateral patellar and lateral collateral ligaments, but even with severe effusion it may be difficult to palpate. Overlying and adjacent soft tissue structures obscure palpation. Effusion of the LFT joint, although rare, is an important palpation finding that should be investigated carefully.

Deep palpation of the medial collateral ligament and the medial patellar ligament with the limb in flexion may elicit a pain response in horses with stifle lameness, but it probably is not specific for the source of pain in the stifle. The medial collateral stress test is perhaps the most reliable manipulative test of the stifle, although horses with lower limb lameness also may respond. With the leg in partial flexion, the shoulder or one hand is used as a fulcrum on the lateral aspect of the stifle, and the distal extremity is pulled laterally, thus placing valgus stress on the stifle (Figure 6-25). Care should be taken because horses may resent this manipulative test. If possible, the valgus motion should be applied by using the shoulder as a fulcrum and both hands on the crus, thus eliminating possible false-positive results from the lower limb. Patellar manipulation may cause a pain response, particularly in horses with

Fig. 6-24 • The medial femorotibial joint (right stifle, cranial view) is the most common location for osteoarthritis of the stifle joint and is palpated medially (needle in joint) between the medial patellar ligament and the medial collateral ligament. Normally a depression is present at this location, but a bulge from effusion can be palpated in this horse.

Fig. 6-26 • Used as a static or provocative test, patellar manipulation is performed by placing the palm of the hand over the cranial aspect of the patella and manually forcing the patella proximally several times in succession. This maneuver can exacerbate pain from conditions of the patella and femoropatellar joint and forces the distal femur in a caudal direction. Pain from soft tissue injuries such as patellar, cruciate, or collateral ligament tears and osteoarthritis of the femorotibial joints can be exacerbated, but false-negative and false-positive results are common. (Courtesy Carolyn Arnold, College Station, TX.)

Fig. 6-25 • The valgus stress test of the stifle is difficult to perform and is accomplished by using a hand (shown) or shoulder as a fulcrum. This test can be done during static examination or a provocative test followed by trotting (see Chapter 8).

femorotibial joint disease. During this procedure, caudal movement of the femur also may exacerbate cruciate injuries. With the limb on the ground in a weight-bearing position, the clinician's hand is placed on the distal aspect of the patella, and the patella is forced upward (Figure 6-26). Theoretically during this test, numerous movements of the stifle are induced. The patellar ligaments are stretched, the patella is forced proximally, and on release the patella rapidly moves distally against the trochlear ridges, and the femur is forced caudally. Tests to assess cruciate ligament damage have been described but are dangerous to perform, and I have not found them particularly useful.¹⁰ Complete tearing of the cruciate or collateral ligaments is rare, and partial tearing does not cause clinically detectable instability. In horses with severe lameness and gross stifle instability, it is obvious that the stifle is the source of lameness, and pain usually prohibits manipulation.

Crus

The examiner should palpate the crus using both hands with the limb bearing weight. Subtle swelling of the medial aspect of the tibia can be palpated, but palpation of the caudolateral aspect of the tibia, the area in which stress fractures are diagnosed most frequently, is limited. Often no palpable abnormality is associated with a stress fracture. Any small wound or any form of swelling should be thoroughly investigated for the possibility of underlying bone damage, such as an occult tibial fracture. The veterinarian should palpate the caudal soft tissues.

Fig. 6-27 • **A**, Palpation of the medial aspect of the tibia in a flexed position or **B**, tibial percussion in the standing position sometimes elicits pain in horses with tibial stress fractures, but false-positive results are common.

Proximally, the musculotendinous junction of the gastrocnemius muscle is a rare site of pain. The common calcaneal tendon is assessed. Swelling may indicate damage to any one of the contributing tendons. Effusion of the tarsal sheath causes swelling just proximal to the tarsus, at the caudal aspect of the crus, and should be differentiated from bog spavin. Deep palpation of the medial and caudal aspects of the crus is performed with the limb elevated (Figure 6-27). Horses with tibial stress fractures or those with spiral fracture or other tibial trauma may show a pain response, but false-positive responses are frequent. Tibial percussion, performed medially by using a clenched fist (knuckles) as a hammer, may elicit a pain response in horses with stress fractures, but many normal horses resent this test.

Tarsus

Five common swellings of the hock are important to differentiate, but hock swelling is not synonymous with hock pain. *Capped hock* is swelling located at the point of the hock (the proximal aspect of the calcaneus) and usually is an incidental finding, but in some horses the condition does cause lameness (Figure 6-28). The most common form involves the development of firm, fibrous subcutaneous tissue in the false bursa that lies over the point of the hock. This is a common area for abrasions and excoriation, and fibrous tissue formation results in a blemish but usually no lameness. Horses may be sensitive to palpation if the area has been traumatized recently. Infection or trauma leading to osteitis of the calcaneus can cause a clinically important capped hock and severe lameness. In these horses the problem involves the calcaneal bursa, located between the common calcaneal tendon and the calcaneus. If surrounding soft tissue swelling is minimal, fluid distention of the calcaneal bursa may be felt by

Fig. 6-28 • Capped hock, a firm fibrous swelling of the proximal aspect of the calcaneus (point of the hock), is considered a blemish, but with effusion of the calcaneal bursa (not shown), lameness is substantial.

ballottement. The bursa can be felt both medially and laterally at the proximal aspect of the calcaneus. Lateral, or less commonly, medial dislocation (luxation) of the SDFT results in similar swelling, but in an acute situation, lameness is present. Careful palpation may reveal the SDFT coursing laterally (Figure 6-29), unless excessive soft tissue swelling is present.

Fig. 6-29 • Lateral dislocation (luxation) of the superficial digital flexor tendon. Instead of attaching to the tuber calcanei, the superficial digital flexor tendon (arrows) is now located lateral to the point of the hock. Initial swelling makes this diagnosis difficult.

Effusion of the tarsal sheath, *thoroughpin*, must be differentiated from bog spavin (see following text). Tarsal tenosynovitis causes swelling both medially and laterally in the depression between the calcaneal tendon and the caudal aspect of the tibia (Figure 6-30). With severe effusion of the tarsal sheath, fluid distention can be palpated distal to the hock on the medial aspect. Thoroughpin usually is an incidental finding, seen most commonly in Western performance horses, but acute lameness accompanied by tarsal tenosynovitis can indicate strain or injury of the sheath, often associated with adjacent bony injury. Unusually, swelling in the distal, caudal aspect of the crus identical to that seen with classic thoroughpin is seen, but communication with and concomitant swelling of the tarsal sheath are absent.

The term *spavin* refers to “any disease of the hock joint of horses in which enlargements occur, often causing lameness ... the enlargement may be due to collection of fluids or to bony growth.”¹¹ *Bog spavin* is fluid distention of the tarsocrural joint capsule. The tarsocrural joint has four outpouchings: dorsolateral, dorsomedial, plantarolateral, and plantaromedial. All joint pouches may be distended, although the dorsomedial and plantarolateral pouches are large and most prominent (Figure 6-31). With ballottement, fluid can be pushed between pouches on the dorsal or plantar aspects, thus differentiating this condition from thoroughpin.

Bone spavin refers to fibrous and bony swelling that results from chronic osteoarthritis of the proximal intertarsal, centrodistal, and tarsometatarsal joints. This swelling

Fig. 6-30 • Thoroughpin, swelling located in the distal, caudal aspect of the crus, usually is caused by distention of the tarsal sheath and must be differentiated from effusion of the plantarolateral pouch of the tarsocrural joint (bog spavin).

Fig. 6-31 • Moderate-to-severe tarsocrural effusion, bog spavin, in this draft filly was caused by osteochondritis dissecans of the cranial intermediate ridge of the distal aspect of the tibia. Distention of the large dorsomedial pouch and swelling of the dorsolateral, plantarolateral, and plantaromedial pouches was present.

Fig. 6-32 • Bone spavin (arrows), fibrous and bony swelling on the medial aspect of the distal hock joint (left hindlimb) caused by chronic osteoarthritis of the distal hock joints, sometimes appears in older sports horses but is rare in young racehorses. The presence of bone spavin should be noted, and this area should be palpated carefully, but horses can have distal hock pain without bone spavin, and horses with bone spavin can have lameness elsewhere in the limb. Previous cunean tenectomy causes chronic fibrosis in this region.

usually is seen in older horses and can be palpated and observed on the medial side of the hock (Figure 6-32). Although the bony enlargement is the result of proliferation, it does not necessarily mean that the horse is lame as the result of the condition. Most horses with distal hock joint pain do not have palpable enlargement medially, and based on radiological evaluation, the most common area of proliferation and bony change is the dorsolateral aspect of the joints. *Blood spavin* is an old term usually meaning enlargement of the saphenous vein,³ but it also may have been used to describe a prominent saphenous vein in horses with bog spavin. Saphenous distention is rare, and the term is not used today. *Occult* or *blind spavin* is an obsolete term used to describe horses with clinical signs of hock lameness but no observable bony swelling.³ *High spavin* is also an obsolete term used to describe bone spavin located close to the tarsocrural joint.³

Curb describes swelling along the distal, plantar aspect of the hock and has often erroneously been blamed on long plantar desmitis. In most horses the swelling is actually enlargement of the SDFT or subcutaneous tissues. The swelling is often firm, but in some horses subcutaneous fluid can be present (see Figure 78-1). In horses with acute severe injury the swelling may feel soft and mushy. In some normal horses the proximal aspect of the MtIV is prominent and should not be confused with curb.

Swelling restricted to the medial or lateral aspect of the hock may reflect collateral ligament injury. Localized heat on the medial aspect of the hock or on the proximal aspect of the metatarsal region may be an important finding.

THE CHURCHILL HOCK TEST

Dan L. Hawkins

The Churchill hock test was developed by Dr. E.A. Churchill in the 1950s as a rapid, noninvasive, specific method to screen and identify distal tarsal pain in athletic horses. Although the test has been used by Dr. Churchill and me primarily in STBs, TBs, endurance horses, and Three Day Event horses, it is equally reliable when applied to other equine athletes.

Digital pressure is applied on the plantar aspect of the head of the second metatarsal bone (MtII) and fused first and second tarsal bones with the limb in a non-weight-bearing position. Abduction of the limb is a positive response. To examine the left tarsus, the clinician approaches the horse facing caudally. The left hindlimb is picked up and brought forward, supported by the clinician's right hand cupped under the fetlock or hoof. Holding the limb so that the hoof is approximately 25 to 30 cm above the ground is most comfortable for the horse. The heel of the left hand is positioned on the proximodorsal surface of the third metatarsal bone (MtIII) while the third phalanges of the index and middle or middle and ring fingers are placed around the medial side of the tarsus to engage the bony ridge formed by the head of the MtII and the first and second tarsal bones (the area of insertion of the cunean tendon) (Figure 6-33). The thumb is rested on the dorsal lateral aspect of the tarsus and the proximal aspect of the MtIII. Gentle, firm pressure is applied to the bony ridge by flexing the phalanges of *only the index and middle fingers* (Figure 6-34). The hand does not squeeze the hock. Pressure is applied three times approximately 1 second apart, each time with increasing intensity to a maximum effort on the third time.

Proficiency requires patience and routine practice. Consistent diagnostic information can be obtained safely from more than 90% of fit racehorses. If the limb cannot be picked up, the test cannot be performed. Fussing and repeatedly flexing the hock and limb in an agitated manner while the procedure is performed should not be misinterpreted as a positive response.

The Churchill hock test is useful for horses that are not visibly lame but for which the trainer or rider has a complaint that the horse is doing something uncharacteristic during work or competition associated with decreased performance. The horse may have a changed attitude toward work, lugs in or out, is rough in the turns, refuses to change

Fig. 6-33 • Correct left hand placement in the left proximal metatarsal region to perform the Churchill hock test. (Courtesy Dan L. Hawkins, Gainesville, FL.)

Fig. 6-34 • The Churchill test is demonstrated on an anatomy specimen. The index and middle fingers are flexed and positioned on the bony ridge formed by the third metatarsal bone and the fused first and second tarsal bones, and the heel of the hand rests on the proximodorsal aspect of the third metatarsal bone. The thumb rests against the dorsolateral aspect of the tarsus. (Courtesy Dan L. Hawkins, Gainesville, FL.)

leads, stops at jumps, jumps to one side, or is stiff going in one direction. Although these horses cannot be blocked out at a slow gait, the Churchill hock test may suggest the presence of distal hock joint pain.

SAPHENOUS FILLING TIME

Mike W. Ross

The veterinarian should assess the saphenous vein filling time. Blood flow in the saphenous vein is prevented using digital compression in the proximal metatarsal region, and the blood accumulated in the vein over the tarsocrural joint is pushed proximally to completely collapse the vein. The finger compressing the vein distal to the hock is then removed, and the time it takes for the saphenous vein to fill is observed. Normally, it takes less than 1 second for the vein to fill, but in horses with reduced circulation, prolonged filling time is seen. Pulse quality of the dorsal metatarsal artery, located on the dorsolateral aspect of the MtIII just dorsal to the fourth metatarsal bone (MtIV), can be useful, especially if the history suggests lameness is caused by vascular compromise. The arterial pulse quality is compared with that in the contralateral limb.

Metatarsal Region

The veterinarian should palpate the digital flexor tendons and SL. Tendonitis is unusual in the hindlimb, but occasionally SDF tendonitis occurs in the proximal metatarsal region. This is most common in horses with curb, and tendonitis progresses distally to involve the metatarsal area. The hock angle is evaluated carefully. Occasionally horses with severe curb or those with SDF tendonitis of the metatarsal region have a reduced hock angle (obvious unilateral sickle-hocked conformation), indicating loss of support in the SDFT. Once a general palpation for the presence of heat, swelling, and exostoses associated with the MtIII, the MtII, the MtIV, and the proximal aspect of the DFTS has been completed, the limb is lifted and deep palpation is performed. The clinician should carefully palpate the origin and body of the SL, keeping in mind that both false-positive and false-negative responses can occur (Figure 6-35). Much of the palpation of the SL laterally is indirect, because the MtIV hides the origin and proximal aspect of the body. Because the presence of the splint bones and dense metatarsal fascia prevents substantial swelling, or at least the clinical recognition of swelling of the SL, even mild swelling in the proximal, medial metatarsal region should be carefully interpreted. With the limb in flexion, the axial borders of splint bones are palpated. The dorsal aspect of the MtIII should also be assessed with the limb in flexion, because bony injury of the MtIII does occur and includes dorsal cortical trauma from external injury or interference, dorsal cortical and spiral fractures, and proximal dorsolateral fractures.

Metatarsophalangeal Joint

Many of the common problems of the metatarsophalangeal (MTP) joint, such as short, midsagittal fractures of the proximal phalanx, sesamoiditis, maladaptive or nonadaptive remodeling of the MtIII, and osteochondrosis, cause very few clinical signs, and although palpation is quite important, diagnostic analgesia is often needed to localize pain to

Fig. 6-35 • Deep palpation of the proximal aspect of the suspensory ligament can be performed only with the limb in flexion. The close association of the suspensory origin to the Churchill site explains the need to differentiate proximal plantar metatarsal pain from distal hock joint pain using diagnostic analgesia. (Courtesy Howard “Gene” Gill, Pine Bush, New York.)

this area. Nonetheless, careful palpation of the fetlock region is mandatory. Some horses have concurrent MTP joint and stifle pain, and when suspicious findings exist in one site, the veterinarian should look carefully at the other for additional, secondary, or complementary problems.

The MTP or hind fetlock joint is evaluated with the limb bearing weight and in flexion. The clinician should assess the MTP joint capsule and the DFTS for the presence of effusion or fibrosis (Figure 6-36). Incidental effusion of both the MTP joint and the DFTS is common in the hindlimb of older performance horses; therefore this finding should not be overinterpreted. In younger horses, particularly racehorses, the presence of effusion can be an important clinical sign associated with osteoarthritis or other problems and should be interpreted accordingly. The clinician should carefully palpate for the presence of heat and mild swelling over the surface of both PSBs, subtle but important signs of sesamoiditis. Sesamoiditis is more prevalent in the hindlimb but can be difficult to detect, and advanced imaging often is necessary for diagnosis. The digital pulse amplitude should be assessed.

With the fetlock joint in flexion, the veterinarian should palpate the proximal, dorsal aspect of the proximal

Fig. 6-36 • The metatarsophalangeal joint region often is overlooked during lameness examination. This joint should be palpated carefully with the limb in the standing and flexed (*shown*) positions. (Courtesy Ross Rich, Cave Creek, Arizona.)

Fig. 6-37 • Palpation of the proximal, dorsal aspect of the proximal phalanx can elicit pain in horses with incomplete mid-sagittal fracture of the proximal phalanx. In trotters, interference injury from the ipsilateral front foot causes pain and swelling in this region. (Courtesy Ross Rich, Cave Creek, Arizona.)

phalanx for the presence of pain or exostoses (Figure 6-37) and should apply pressure to the PSBs, avoiding aggressive compression, which may cause false-positive results. The range of motion of the MTP joint is noted.

Pastern

When the limb is elevated, the reciprocal apparatus causes constant flexion of the digit, which makes palpation of the

plantar aspect of the pastern exceedingly difficult. Subtle swelling in the plantar aspect of the pastern is easy to miss. Bony and soft tissue structures should be palpated with the horse in the standing position, and the veterinarian should note the same clinically important areas that were pointed out for the forelimb. High and low ringbone (osteoarthritis of the proximal interphalangeal and distal interphalangeal joints, respectively), osteochondrosis of the pastern joint, and soft tissue problems such as SDF branch tendonitis, distal sesamoidean desmitis, and plantar injury of the pastern joint occur, but with reduced frequency when compared with the forelimb.

Foot

A similar approach to the evaluation of the hind foot as that described for the front foot is used. I spend considerably less time evaluating the hind foot than the front foot, unless the history or horse type dictates otherwise, because this area is relatively infrequently the source of pain. In the draft horse, hind foot pain is as common as in the forelimb, and therefore the hind feet merit considerable attention. Unless specifically indicated by the lameness history, or the horse is severely lame without an obvious cause in the upper limb, I do not routinely perform a hoof tester examination of the hind feet. Pressure with hoof testers over the frog and across the heel in a hind foot often causes a false-positive response in normal horses. The position needed to perform an unassisted hoof tester examination in the hindlimb can be dangerous. The presence of an assistant to elevate the limb may obviate some of the risk.

The examiner should assess the shape, balance, and contour of the foot and observe the shoe (or lack of one) carefully. Hoof angle in the hindlimb ranges from 48 to 58 degrees, and the hoof and pastern axis should be straight. A common finding is a low or underrun heel. An interesting relationship between a low heel and the presence of PSD has been noted.² In these horses a lateral radiographic image of the foot shows that the plantar aspect of the distal phalanx is lower than the dorsal aspect.² Shoe wear is extremely important in the hindlimb and can give clues to the source of lameness. For instance, horses with distal hock joint pain tend to stab the lower hindlimb during advancement, causing excessive wear of the lateral branch of the shoe (Figure 6-38). Other causes of lower hindlimb lameness, such as osteoarthritis of the MTP joint, can cause a similar gait, but usually abnormal shoe wear is less pronounced. Horses with stifle lameness often wear the medial branch of the shoe. The presence of heel and toe caulks or borium causes additional shear stress on many of the lower limb joints and can exacerbate lameness.

THE ROLE OF PHYSICAL EXAMINATION IN THE LAMENESS EXAMINATION

Body temperature may assist with a clinical diagnosis. The normal temperature range is 37.5° to 38.6° C (99.5° to

Fig. 6-38 • It is imperative to observe the hind shoes for wear during lameness examination. This right hind shoe (lateral is to the right) has wear along the dorsal and lateral aspects (lateral aspect of toe grab and fullering are worn) consistent with a lower hindlimb lameness, such as distal hock joint or proximal metatarsal region pain.

101.3° F), although in a foal the upper limit may normally be slightly higher. Body temperature in foals rises more abruptly than in adult horses in response to stress, infection, and inflammation. Thus transport of a foal may cause transient low-grade pyrexia, but fever in an adult horse after transport is abnormal. Localized infection in a foal usually causes pyrexia but rarely does so in an adult. The examiner should not *exclude* infectious arthritis in an adult horse simply because fever is *not* present. However, adult horses usually are pyrexemic during the early stages of cellulitis or lymphangitis.

Elevation in the pulse and respiratory rates often accompanies severe lameness because of pain. Systemic diseases such as endotoxemia may cause abnormal vital parameter findings in any horse and can lead to conditions such as laminitis.

It is important to remember that diseases of other body systems can cause clinical signs that mimic lameness or cause true gait deficits. For instance, abnormal or stiff gaits can be seen in horses with pleuritis and peritonitis, abdominal, sublumbar, inguinal, thoracic inlet, and pectoral abscesses or tumors. Proliferative new bone associated with hypertrophic osteopathy may be associated with a thoracic or abdominal mass. If an unusual situation arises, the veterinarian should step back and think of the exception rather than the rule, because the “red herring” may be just around the corner.

Chapter 7

Movement

Mike W. Ross

"The best time for examining a lame horse is while he is in action. An attendant should lead him on a trot, preferably on hard ground, in a straight line, allowing him freedom of his head, so that his movements may all be natural and unconstrained."

A. Liautard, 1888¹

References

1256

It would be difficult to improve on Liautard's insistence that the lame horse be examined during movement or his description for how it is best accomplished. Although all parts of the lameness examination are important, the key is the determination of the limb or limbs involved. Not all horses with musculoskeletal problems exhibit lameness that is perceptible under normal conditions, or even by use of high-speed or slow-motion cinematography, gait analysis, or other sophisticated imaging devices. Under most circumstances, however, lameness from pain or a mechanical defect in gait is discernible, and the essence of the lameness examination is to determine the source of the pain. This discussion includes relevant experimental findings to support clinical observations, but sometimes experimental findings are confusing rather than informative.

GAIT

Gait, defined as the "manner or style of walking"² or "the manner of walking or stepping,"³ is used to describe the speed and characteristics of a horse in motion. The *natural gaits*, those exhibited when a horse is free in a field, are the walk, trot, and gallop.⁴ The canter is a collected gallop. Other gaits including the pace, running walk, rack (a singlefoot or broken amble), fox trot, and amble are *artificial gaits*, although some pacers pace "free-legged" (without the use of hobbles) while on the track, either at a slow speed or racing speed, and occasionally a Standardbred (STB) paces free-legged in a field. In some instances a trotter switches from a trot to the pace, but this change usually is exhibited while the horse is performing at speed and may be associated with lameness or interference. Lame trotters usually "make breaks," going off stride, by switching (breaking) from the trot to the gallop.

The term *beat* describes the number of foot strikes in a single stride cycle regardless of whether one or more feet strike the ground simultaneously. The following abbreviations are used for limbs: left forelimb (LF), right forelimb (RF), left hindlimb (LH), and right hindlimb (RH). The walk is a four-beat gait in which all four feet strike the ground independently without a period of suspension (in which no feet are on the ground). Depending on the part of the stride during which observations begin, the walk can appear to be lateral or diagonal. In general, in a lateral gait, both feet on one side strike the ground before the feet on

the contralateral side. In a diagonal gait, one foot strike is followed by a strike of the foot located diagonal and contralateral to the initial foot (e.g., LF followed by the RH).

Lame horses should always be evaluated at the walk. Stride length should be evaluated and compared with observations at the trot. Stride length and sequence of footfalls are easier to see while horses are walking than while they are trotting. Horses with hindlimb lameness may be examined for failure to track up.⁵ Horses normally track up, or overtrack. The hind foot is placed in or in front of the imprint of the ipsilateral front foot. Failure to track up usually is caused by hindlimb lameness or poor impulsion, and the hind foot imprint is seen behind that of the ipsilateral front foot.⁵ Although unusual, occasionally a horse will be observed to pace while walking, a finding that may indicate the presence of neurological disease. In breeds unassociated with the pace or similar gaits, young horses that pace should undergo careful neurological evaluation. Pacing while walking may be completely normal, and in older, "made" horses (horses that have already achieved an upper level of performance) the finding should not be overinterpreted.

Backing is a diagonal, two-beat gait. Horses seldom back naturally, but backing commonly is required of horses during performance events, while exiting from a trailer, or while driving. Backing is useful during lameness examination to evaluate certain gait deficits, such as those associated with shivers, stringhalt, and neurological disease.

The trot is a diagonal, theoretically two-beat gait, and diagonal pairs of limbs move simultaneously. The trot is theoretically a symmetrical gait, meaning both "halves" (beats) of the stride are identical, and at low speed in a sound horse, symmetry is likely achieved. However, at speed, perfect balance and fine management of weight (of the shoes) are necessary for a trotter to be perfectly symmetrical. There is a moment of suspension between impact of each diagonal pair of limbs. Some elite dressage horses do not have a two-beat gait but show advanced diagonal placement. This means that the hindlimb of a diagonal pair of limbs lands first and therefore is the only limb bearing weight. Hindlimb lameness is present in a higher percentage of horses that perform at speed at the trot compared with galloping horses because of differences in weight distribution in the trot and gallop. Compensatory lameness develops in the diagonal paired limb. LF lameness predisposes to RH lameness. Interference between limbs is more common in horses that trot at speed when compared with those that gallop. Likewise, hindlimb lameness is relatively common in dressage horses.

The pace is a symmetrical, lateral, two-beat gait predominantly in STB racehorses and is characterized by movement of lateral pairs of limbs simultaneously (LH and LF; RH and RF), with a moment of suspension between lateral pairs. Pacers also have a high percentage of hindlimb lameness, but compensatory lameness usually develops in the lateral paired limb. RH lameness predisposes to RF lameness.

The gallop or run is a four-beat gait. In the gallop and the canter the horse leads with the LF or RF, the forelimb that strikes the ground last in the stride sequence. An unrestrained horse usually leads with the LF while turning

to the left, or the RF while turning to the right. Fatigue also plays a role. A Thoroughbred (TB) racehorse racing counterclockwise leads with the LF on the turns but immediately after entering the stretch switches to the right lead. Failure to switch leads or constantly switching leads in the gallop or canter may reflect fatigue or lameness.

In a *left* lead gallop, the RH strikes the ground first, followed in sequence by the LH, RF, and LF, followed by a period of suspension. When a horse is on the right lead, the RF strikes the ground last, propelling the horse into the suspension phase of the stride. It is often assumed that a horse with RF lameness is reluctant to take the right lead. However, bone stress measured in the radius and the third metacarpal bone (MCIII) is greater on the nonlead (trailing) forelimb, and thus a lame horse may change leads to protect the nonlead forelimb.⁶ Ground reaction forces (GRFs) are greater in the trailing (nonlead) forelimb, a fact that supports the clinical observation that horses with forelimb lameness may select leads to protect the lame forelimb. A horse with RF lameness may prefer the right lead, allowing the LF to assume the greater forces and bone stress.⁵

The canter (lope) is a three-beat gait. In left lead canter the RH strikes the ground first, then the LH and RF land simultaneously, followed by the LF and then a period of suspension. A horse reluctant to take a lead may be trying to compensate for hindlimb lameness. In the right lead the LH must absorb a considerable amount of concussion and then generate propulsive forces. Proneness of this limb to fatigue seems logical, but a consistent change in stride characteristics of fatigued horses to protect the LH was not seen.⁷ Although the LH strikes the ground first, stance time, flexion of the upper limb joints, and GRF are greater in the RH.⁵ It could be assumed that a horse lame in the RH would be reluctant to take the right lead and may prefer the left lead.⁵ Lead and stride characteristics of fatigued and lame horses are complex because of asymmetry of the gait, and forelimb and hindlimb problems could account for failure or reluctance to take a particular lead and inappropriate lead switching.

Young horses early in training or trained horses that are lame may exhibit a disunited canter. The horse may spontaneously change legs behind, but not in front. In changing from left to right lead canter, or vice versa, the forelimbs and hindlimbs should change simultaneously. Horses with back pain or hindlimb lameness may be reluctant to change leads, or may change in front but not behind.

The Lameness Examination: Which Gait Is Best?

The trot is the most useful gait to determine the location of the lame limb or limbs. Forelimb lameness in particular is difficult to observe at the pace, especially in horses that are led in hand. Lame trotters may pace, supporting the supposition that the pace is an easier gait in a lame STB. I have seen horses with severe forelimb lameness at the trot that looked barely lame when pacing.

Comparing Lameness Seen at the Walk and Trot

Although lameness score should be determined when trotting a horse (see later), it is useful to compare gait deficits at the walk and trot. In horses with forelimb lameness, an exaggerated head and neck nod may be observed while

walking horses with upper limb lameness (genuine shoulder region pain, for instance), and, in fact, head and neck excursion may be more pronounced than that seen while the horse is trotting. Some horses may exhibit odd gait deficits while walking, but deficits may abate at the trot. Horses with rare upper forelimb pain from rib fractures or anomalies may manifest abduction of the forelimb during protraction at the walk but not the trot. The stance phase of the stride is relatively longer at the walk than at the trot. The deep digital flexor tendon and the collateral ligaments of the distal interphalangeal joint are stressed maximally with extension of the distal interphalangeal joint. Thus with severe injuries of either structure lameness may be more severe at the walk than at the trot because of greater extension of the distal interphalangeal joint associated with the relatively long stance duration.⁵ Horses with hindlimb lameness characterized by a shortened caudal phase of the stride at the walk but shortened cranial phase at the trot often have upper limb lameness, such as that caused by pelvic fractures or osteoarthritis of the coxofemoral joint or from severe pain originating from the foot. In general, horses that have limb flight characteristics that differ between walk and trot should be evaluated carefully because in my experience they often have bona fide pain originating from the upper limb or are affected with an unusual mechanical or neuromuscular deficit.

Relevance of Lameness at a Trot in Hand

Is lameness seen at a trot in hand the same lameness that compromises performance at speed? Is the lameness seen at a trot in hand in a jumping horse the same problem that causes the horse to refuse fences? The answer is usually, but not invariably, yes. For instance, I have seen many STBs show subtle unilateral hindlimb lameness at a trot in hand, but when the horse was later examined at the track and hooked to a cart, pronounced contralateral hindlimb lameness was noted. Differences include the track surface, the act of pulling a cart, the additional weight of the driver, and a faster gait. Lameness often is evaluated on a smooth hard surface useful in exacerbating even subtle problems, but most horses perform on softer surfaces, when other problems may be apparent. More than one lameness problem may exist—one evident at a trot in hand and another while the horse is ridden or driven. Horses can show lameness from one problem when trotted in a straight line but lameness from an entirely different problem while being trotted in a circle. The answer to the first question is complex because performance itself entails the inextricably intertwined relationship between horse and rider or driver and the possible presence of compensatory and coexistent pain. Ideally, to evaluate the role of lameness on poor performance, horses would be evaluated at the speed, at the gait, and in the manner in which they perform, conditions that usually are not always possible to reproduce.

Horse Temperament and Lameness Examination

Safety of the handler, observers, and the horse must always be considered throughout a lameness examination, and with a difficult horse the examination may need to be modified, especially on cold, windy days. In some female horses and geldings, judicious use of the tranquilizer acetylpromazine (0.02 to 0.04 mg/kg intravenously [IV]) permits continuation of the examination. I avoid use of

this tranquilizer in stallions, although the possibility of paraphimosis is remote. Low doses of sedatives such as xylazine can be used (0.15 to 0.30 mg/kg IV) in stallions or other horses but can produce mild ataxia. Detomidine may be a better choice than xylazine because the drug lasts longer, thus allowing diagnostic analgesic procedures to be performed.⁵

I try to avoid using tranquilization and sedation, although some clinicians use them frequently and report that lameness in most horses may be more pronounced and easier to observe. Mild muscle relaxation may reduce the tendency of the horse to guard the lame leg. Mild analgesic effects of sedatives may mask mild pain, and in racehorses care must be taken to avoid use of drugs that may cause a positive result in a drug screen. In big moving, exuberant Warmblood horses, especially dressage horses (particularly stallions), sedation may be essential to accurately assess lameness.⁵

Leading the Horse during Lameness Examination

The horse must be led with a loose lead shank so that it can move the head and neck freely. It is impossible to see a head nod in a fractious or excited horse that is held tightly. Use of a chain lead shank over the nose facilitates control but is resented by some horses, and use of a bridle with a lunge line attached may be preferable.⁵

Horses should move at a consistent speed, not too fast and not too slow. A lazy horse may need encouragement with a whip. Constantly changing speed can make assessment of lameness difficult, but occasionally, assessing a horse during deceleration may reveal useful information about the existence of subtle lameness.⁵ A horse may have to be trotted up and down many times. It is sometimes useful for the examiner to lead the horse to assess subtle forelimb lameness, because gait abnormalities may become more obvious.

Surface Characteristics and Lameness Examination

The horse should be examined on a smooth, flat surface. I prefer a hard surface, such as pavement or concrete that creates maximal concussion and may exacerbate subtle lameness. However, the clinical relevance of mild lameness seen on hard surfaces, especially on turns, should not be overinterpreted. Many horses that are actively competing successfully show mild lameness on hard surfaces; it is important to understand that the horse does not perform on a surface of pavement, and foot strike patterns and gait could be much improved if the horse performs on firm but forgiving surfaces. Crushed rock, cobblestone, deep sand, or undulating grassy areas and potentially dangerous slippery surfaces should be avoided.

It is important that the surface be nonslip because some horses appear to lack confidence while moving on hard surfaces and alter the gait. In these situations, horses may shorten the stride for protection rather than from lameness.⁵ Horses with studs or caulk on the shoes may develop induced lameness unrelated to the baseline lameness when trotting on hard surfaces.⁵

Ideally the gait on hard and soft surfaces should be compared, to help differentiate soft tissue from bony problems. Horses with foot pain usually perform worse on a hard surface. Lameness from soft tissue injuries, such as suspensory desmitis or tendonitis, tends to be worse on soft

or deep ground. To evaluate lameness during transition from a hard to a soft surface and vice versa, a horse can be examined while circling on a lunge line in an area where both surfaces coexist side by side.⁵ Care must be taken to prevent the horse from slipping during this examination.

DETERMINATION, GRADING, AND CHARACTERIZATION OF LAMENESS

Six basic steps are necessary to determine, grade, and characterize lameness. The clinician should determine the following:

1. Primary or baseline lameness or lamenesses
2. Possibility of involvement of more than one limb and presence of compensatory (coexistent) lameness
3. Classification of lameness as supporting, swinging, or mixed
4. Grading of lameness or lamenesses
5. Alteration of the cranial or caudal phase of the stride
6. Presence of abnormal limb flight

The *primary* or *baseline* lameness is the gait abnormality before flexion or manipulative tests are used. The practitioner attempts to abolish baseline lameness using analgesic techniques. Lameness in more than one limb may complicate determination of the worst affected limb. It is important to trot a horse even if it is quite lame at a walk, unless an incomplete or stress fracture is suspected. A horse may take a short step with a limb at walk, or can appear very lame, but trot reasonably soundly. Horses with scratches (palmar or plantar pastern dermatitis) or superficial wounds in the palmar or plantar pastern may appear quite lame at walk but trot relatively well. A STB pacer may walk extremely shortly both in front and behind but pace or trot without lameness. However, only the degree of lameness usually differs between a walk and trot. A horse may appear sound at walk and trot in hand, but lameness may be apparent trotting in a circle, in hand or on the lunge, or while being ridden. *This lameness now becomes the baseline lameness*, and it is under these conditions that the results of diagnostic analgesia should be evaluated. The clinician should try to recognize if the horse has bilateral forelimb or hindlimb lameness that manifests as shortness of stride or poor hindlimb impulsion, or if concurrent forelimb and hindlimb lameness are present. Moderate-to-severe hindlimb lameness can mimic ipsilateral forelimb lameness, although ipsilateral forelimb and hindlimb lameness also occurs. In these horses the veterinarian should perform diagnostic analgesia in the hindlimb first.

Compensatory Lameness

Compensatory (secondary or complementary) lameness results from overloading of the other limbs as a result of a primary lameness. It must be differentiated from the stride-to-stride compensation by a horse to avoid interference injury because of a gait deficit, or lameness, or to shift weight (load) during examination. A compensatory problem develops as the result of predictable compensation a horse may make *over time* for a primary lameness in a single limb. However, a horse may compensate for lameness in one limb by shortening the stride in another, a stride-to-stride change in gait that is not the result of lameness. For instance, in

some trotters with severe LF lameness, reluctance to extend the LF may induce a compensatory shortening of the cranial phase of the stride in the LH limb, creating what appears to be a hike in the LH. If the veterinarian looks only at the hindlimbs, LH lameness may be diagnosed. A trotter performing at speed with LF lameness is likely to develop compensatory lameness in the RF or RH but not in the LH. However, the horse may appear to be hiking (lame) in the LH to avoid interfering with the LF. Elimination of obvious unilateral forelimb lameness usually resolves an ipsilateral pelvic hike. Most horses with pronounced forelimb lameness examined at a trot in hand will have a concomitant shortening of the cranial phase of the stride in the contralateral hindlimb, giving the false impression of coexistent lameness in this limb and vice versa. Experimental results appear to support this clinical impression. In 6 of 10 horses with stance phase forelimb lameness, compensatory movements of horses created a false lameness in the *contralateral* hindlimb (see following text).⁸ Once forelimb lameness is abolished using diagnostic analgesia, the shortened cranial phase of the stride in the contralateral hindlimb will abate.

It is often difficult to know which lameness came first, but it is important to understand how horses compensate for lameness and which limbs are at risk to develop compensatory problems. Compensatory problems range from obvious lameness to only mild palpable abnormalities that may still compromise performance. Several predictable patterns of compensatory lameness are possible; the most common is bilateral forelimb or hindlimb lameness. Horses with a specific lameness in one forelimb are at risk to develop the same condition in the opposite forelimb. This tendency may not always be compensation for the primary lameness but may reflect simultaneous injury or degeneration of bone or soft tissue of both limbs. Abnormal loading of forelimbs or hindlimbs, faulty bilateral conformation, and the same shoeing or foot conditions all likely contribute to bilateral, simultaneous lameness. In horses with bilateral lameness, eliminating lameness in one limb usually results in pronounced contralateral limb lameness. Bilateral lameness may affect both limbs equally, resulting in a short, choppy gait. The horse may be lame in one limb while being circled in one direction and lame in the contralateral limb in the opposite direction.

Racehorses that gallop are most likely to develop compensatory lameness on the contralateral limb or the ipsilateral forelimb or hindlimb. A TB racehorse with a left metatarsophalangeal joint lameness is most likely to develop a similar problem in the RH but may also develop LF lameness. In a trotter the contralateral limb is most at risk, followed by the diagonal forelimb or hindlimb. If a trotter has a right carpal lameness, the left carpus should be examined carefully; compensatory lameness also may occur in the diagonal LH limb. In a pacer the ipsilateral forelimb or hindlimb should be considered after the contralateral limb. In a pacer with LH lameness the RH and LF are at risk.

The most common compensatory lameness is the same problem in the contralateral limb. However, suspensory desmitis is a common compensatory problem in both the contralateral and other limbs. In a TB racehorse or a jumper with LF lameness, RF suspensory desmitis is common. Primary RH lameness may result in suspensory desmitis in

the RF. It is logical that soft tissue structures are particularly vulnerable to the effects of overload. Superficial digital flexor tendonitis may develop secondary to a primary problem in the contralateral limb. In trotters a common pattern is primary carpal lameness and compensatory osteoarthritis of the medial femorotibial joint in the diagonal hindlimb, or vice versa.

Compensatory lameness also can develop in the same limb. In horses with front foot lameness the suspensory ligament (SL) often is sore, and some horses have suspensory desmitis. In horses with lameness abolished by palmar digital analgesia, most with navicular syndrome, scintigraphic examination revealed increased radiopharmaceutical uptake (IRU) in the proximal palmar aspect of the McIII in 30% of horses, indicating possible abnormal loading of the proximal aspect of the SL (Figure 7-1).⁹ Complete resolution of lameness may not be achieved until high palmar analgesia is performed.

Horses with primary metatarsophalangeal joint lameness often have associated ipsilateral stifle pain, or vice versa.¹⁰ Determination of the primary site of lameness may be difficult without use of diagnostic analgesia and observing that blocking one site abolishes the majority of lameness. This phenomenon may be most common in STBs, but I have recognized it in all types of sport horses and in TB racehorses.

Supporting, Swinging, and Mixed Lameness

Lameness has classically been divided into three categories in an attempt to characterize the motion associated with the lame leg and to assign a cause to the lameness condition. These categories are described and discussed, but I firmly believe that adequate characterization of most lameness conditions is impossible and may be unnecessary.

Supporting limb lameness describes a lameness that results in pain during the weight-bearing phase of the stride. Most lameness conditions are of this type. Supporting limb lameness also has been referred to as *stance phase lameness*, but this term is inappropriate because the swing phase of the stride is also altered.

Swinging limb lameness describes lameness that primarily affects the way the horse carries the lame limb. However, most horses with painful lameness conditions alter the swing phase of the stride in a typical and repeatable fashion, and it is difficult to make a clear separation between supporting and swinging limb lameness. *Swinging limb lameness* should be a term reserved for mechanical defects of gait, such as fibrotic myopathy, upward fixation of the patella, stringhalt, or other lameness conditions causing a mechanical restriction of gait. In these horses, lameness is manifested in the swing phase of the stride with no apparent pain. Unfortunately, the term *swinging limb lameness* often is used inappropriately to describe the gait deficit in horses with painful, supporting limb lameness. Lameness associated with osteochondrosis of the scapulohumeral joint is often described as a swinging limb lameness because of a markedly shortened cranial phase of the stride. Dramatic improvement in the shortened cranial phase of the stride can be achieved by diagnostic analgesia, eliminating pain associated with lameness. Thus the gait deficit is the direct result of pain, and no clear differentiation between supporting and swinging limb lameness can be made. Horses with painful forelimb lameness almost always

Fig. 7-1 • A, Lateral delayed-phase scintigraphic view showing focal, mild increased radiopharmaceutical uptake (IRU) of the navicular bone (*bottom arrow*) and proximal aspect of the third metacarpal bone (McIII; *top arrow*). Normal modeling is seen in the dorsal aspect of the proximal phalanx. **B**, Dorsal delayed-phase scintigraphic image, and **C**, dorsomedial-palmarolateral oblique xeroradiographic image of a dressage horse with lameness abolished by palmar digital analgesia. IRU of the medial aspect of the distal phalanx (*bottom arrow*) corresponds to the area of subchondral radiolucency seen in the xeroradiographic image (**C**, *arrowhead*). Note the focal area of mild IRU involving the proximal aspect of the McIII (*top arrow*, **A** and **B**). Abnormal loading of the suspensory ligament may occur as a compensatory problem in some horses with navicular syndrome or other sources of palmar foot pain.

shorten the cranial phase of the stride, although perhaps not to the extreme as in a horse with authentic scapulo-humeral joint lameness. Horses with any painful hindlimb lameness consistently shorten the cranial phase of the stride, a reliable clinical indicator of which limb is affected, and when pain is abolished, the cranial phase (swing phase) of the stride improves (lengthens). Because the terminology is confusing and often erroneous, I prefer to avoid use of these terms and simply describe lameness as accurately as possible. For instance, describing a horse as grade 2 of 5 LF lame, with a marked shortening of the cranial phase of the stride reminiscent of other horses I have seen with shoulder region lameness, gives the most accurate and useful information.

There is an erroneous tendency to equate a swinging limb lameness with one that is more evident when the lame limb is on the outside of a circle. Upper limb lameness is often presumed yet not confirmed by diagnostic analgesia. It is logical that if a horse is reluctant to swing a limb forward, the lameness may be most prominent when the lame limb is on the outside of a circle. However, many horses with painful weight-bearing lameness show more pronounced lameness with the limb on the outside of a circle, a finding that neither suggests that lameness originates from the upper limb nor indicates the presence of swinging limb lameness (see following text). The outer limbs must stretch further and cover a larger circumference circle than the inside limbs. Slight temporal differences in the stance and swing phases of the inside and outside limbs are necessary to maintain gait symmetry.⁵ Therefore the

stance phase of the stride may be relatively longer for the inside hindlimb, resulting in extension of the fetlock for a longer time and stress on the suspensory apparatus, whereas for the outside hindlimb covering a longer distance in the same time, there may be greater extension of the fetlock for a relatively short time, but still with stress on the suspensory apparatus. Thus pain associated with hindlimb proximal suspensory desmitis is worse in some horses with the lame or lamer limb on the inside of the circle, whereas with others lameness is accentuated with the lame limb on the outside of a circle.

The results of cinematographic analysis of gait in lame horses seem to support reservation of the term *swinging limb lameness* for horses with authentic mechanical gait deficits, rather than those induced by painful lameness. In a horse with a supraglenoid tubercle fracture examined at a trot in hand, a marked decrease in the cranial phase of the stride (protraction) was observed, along with a marked head and neck nod. A markedly shortened stride could be equated with swinging leg lameness, but high-speed cinematography showed that the cranial and stance phases of the stride were shorter than in the sound limb.¹¹ A horse with unilateral semitendinosus fibrotic myopathy had a shortened stride length and a shortened cranial phase of the stride, but the stance phase did not differ from that of the unaffected contralateral limb.¹²

In my experience, most lameness conditions can be considered *mixed lameness*, with changes in gait during weight bearing or the stance phase and during the swing phase of the stride. With the exception of mechanical

defects in gait, I have not been able to categorize the clinical characteristics of most lameness conditions into swinging or supporting limb types. However, it has been suggested that swinging limb lameness is caused by muscle injury; supporting limb lameness is caused by bone, tendon, and ligament injury; and mixed lameness is caused by joint, tendon sheath, and periosteal injury.¹³ A shortened cranial phase of the stride is a common characteristic in forelimb and hindlimb lameness and should not be considered pathognomonic for the location or type of lameness.

DETERMINING THE LOCATION OF LAMENESS

The horse should be observed at both the walk and the trot from the front, behind, and side. I spend most of my time watching the horse move away and then back toward me. Medial-to-lateral limb flight and foot strike can be evaluated only from this perspective, although cranial and caudal aspects of the stride and fetlock drop (see following discussion) can be evaluated only from the side. Most important, evaluation of lameness from this perspective allows the veterinarian to use the horse as a frame of reference. I find it quite useful to evaluate forelimb lameness when the horse is traveling away from me and hindlimb lameness when the horse is traveling toward me. This perspective allows use of the horse's top line to see a subtle head and neck nod or pelvic hike. Only by observing the horse from the side can the cranial and caudal phases of the stride be determined. When first learning to assess lameness from the side, a linear frame of reference, such as a fence or wall in the background, may be helpful to notice head nod and pelvic hike against an immovable background. Application of pieces of tape or other markers to the horse's head or a fixed point on the pelvis can assist recognition of upward and downward movement of that body part.

Independent observation of the forelimbs and hindlimbs is needed to understand whether a horse has forelimb or hindlimb lameness or a combination. These observations then are amalgamated to form a final clinical impression.

Recognition of Forelimb Lameness

Forelimb lameness often is easier to recognize than hindlimb lameness. *Understanding the concept of the head nod is vital to the correct interpretation of equine lameness.* The head and neck elevate or rise when the lame forelimb is bearing weight or hits the ground and nod down or fall when the sound forelimb hits the ground. "When the [forelimb] is the lame one, the movements of the foot and head occur somewhat in unison. When the lame foot is raised, the head is elevated, but only to fall when the sound leg is brought to a rest."¹ Some clinicians find it easier to appreciate the head nod down, whereas others find it easier to recognize elevation of the head.

When slow-motion videotape of lame horses is evaluated, it is immediately obvious that the elevation of the head and neck is much easier to see than the head nod down. In slow motion the horse appears to be elevating the head and neck just before the lame limb hits the ground, and then, during the later portion of the support or stance phase, the head and neck nod down. In fact, in

slow motion it is head and neck elevation from a baseline level and later settling of the head and neck (nod downward) that are seen. The head returns or settles to baseline, giving the distinct impression that the horse is unloading the lame limb rather than loading the sound limb. The head and neck nod occurs as the contralateral limb begins the support or stance phase. Both head elevation and falling are present, but head elevation is much easier to detect when it occurs in unison with the lame limb hitting the ground. It is likely that a combination of visual clues allows the clinician to decide the primary forelimb lameness. Quantification of lameness and description of the actions of the lame and compensatory limbs have been attempted using gait analysis systems. In horses with amphotericin-induced carpal lameness, head movements were the most consistent indicator of lameness, followed by sinusoidal motion, or a rising and falling action, of the head and withers.¹⁴ The motion of the lame limb was assessed, and a falling of the head and withers during the support phase of the lame limb was noted, contrary to clinical perception and evaluation of slow-motion videotape of lame horses. It was suggested that an uncoupling of the weight from the lame forelimb and a "free fall-like" phenomenon occurred during weight bearing.¹⁴ The problem with this description is that it considers only the lame limb and is confusing. When evaluating a lame horse, the observer sees both forelimbs. During the later portion of the support phase of the lame limb, the sound limb is in the later portion of the swing phase and beginning the support or stance phase. Thus the head and withers drop described experimentally appears to occur concomitantly with the sound limb hitting the ground. The observer perceives the early portion of the stance or support phase.

In general, a good correlation between clinical evaluation of forelimb lameness and that described using motion analysis has been observed. There was complete agreement between clinical determination of location of forelimb lameness and that detected by motion analysis using a computerized three-dimensional motion measurement system. However, the degree of lameness differed in 6 of 29 horses.¹⁵ In a more recent study subjective forelimb lameness grades were significantly associated with kinetic parameters, and vertical force peak and impulse had the lowest coefficients of variations and highest correlations with subjective lameness score.¹⁶ In fact, kinetic parameters using GRFs measured by force plate analysis detected subclinical lameness not seen by a trained observer, a finding that may indicate that quantitative lameness analysis may be useful in horses with subtle lameness.¹⁶ The maximal vertical acceleration of the head was the best indicator of forelimb lameness.¹⁷ Although horses with forelimb lameness shifted weight in a caudal direction to the diagonal hindlimb, the amount of withers motion was minimal. The authors reasoned that the tremendous mobility of the head and neck, allowing the horse to asymmetrically elevate the neck and thus load the nonlame forelimb, accounted for the lack of withers movement and the horse's adaptation to forelimb lameness.¹⁷ A similar compensatory ability is not present in the hindlimb. Vertical displacement of the tuber coxae and forward motion or translation of the pelvis occur in horses with hindlimb lameness, because a mechanism such as head and neck movement does not exist.¹⁷ In a computer-generated model of a trotting horse the

dynamic effects of head and neck movement accounted for the majority of load shift to the contralateral forelimb and diagonal hindlimb in horses with unilateral forelimb lameness.¹⁸ Load shift and compensation by the diagonal hindlimb in horses with unilateral forelimb lameness lend support to the clinical findings of compensatory lameness in the diagonal limbs in trotters.

Instrumented shoes have been used experimentally to study motion in horses by quantifying GRF but have had limited clinical use.^{19,20} Lack of correlation between an in-shoe system and force plate analysis was disappointing, and neither research nor clinical application of the system was recommended.²¹ Although these systems are not currently widely available, in the future these or similar systems may be useful to objectively assess lameness and the response to diagnostic analgesic techniques in clinical patients. A remote monitored sensor-based accelerometer-gyroscopic (A-G) system showed good correlation in horses with either forelimb or hindlimb lameness when compared with a video-based motion analysis system used in horses moving on a treadmill.²² Hindlimb lameness was consistently higher (in grade) using the A-G system, but the system yielded false-positive results in horses with concurrent forelimb lameness.²² However, for a skilled observer, direct observation of the horse may be more accurate than kinetic or kinematic analysis of gait when a horse is lame in more than one limb.⁵

Recognition of Hindlimb Lameness

Historically descriptions of hindlimb lameness have been confusing. An important principle in the recognition of hindlimb lameness is the concept of the *pelvic hike* or asymmetrical movement of the pelvis. This has also been termed *hip hike*, but I prefer the term *pelvic hike* because it accurately describes how the pelvis moves in a horse with unilateral hindlimb lameness. The entire pelvis, not just the lame side of the pelvis, appears to undergo elevation. Because the horse has two “hips” and only one pelvis, the term *pelvic hike* seems preferable. Pelvic hike is the vertical elevation of the pelvis when the lame limb is weight bearing. In other words, the pelvis “hikes” upward when the lame limb hits the ground and moves downward when the sound limb hits the ground. The “haunch settles downward when the sound leg touches the ground....”¹ Some clinicians find it easier to see the downward movement of the pelvis, on the side of the lame limb, rather than the pelvic hike.⁵ It may be simpler to determine which side has the most movement, rather than looking for either a hike or a drop.⁵ The clinician must keep in mind that the pelvic hike is the clinical impression of *the change in height of the pelvis*, not the absolute or measured height. It is the shifting of weight or load that occurs as the horse tries to reduce weight bearing (unload) in the lame limb and transfer weight (load) to the sound limb. The ease with which this can be seen depends on the horse’s tail carriage; in a horse with a tail set on high and that is also carried high, this may completely obscure movements of the pelvis.

Another explanation for asymmetrical movement of the pelvis involves one of the protective or compensatory mechanisms used by the horse to assist in breakover and minimize load on the lame limb. Many horses with hindlimb lameness drift away from the lame limb toward the sound limb. Drifting may decrease the magnitude of

the observed pelvic hike, but more important, it makes the lame side look lower than the sound side. This is why it is important to watch the entire pelvis as a unit rather than the individual sides of the “hips.”

In most horses with hindlimb lameness, particularly those without a substantial tendency to drift away from the lame limb, the elevation of the pelvis (pelvic hike up) when the lame limb hits the ground surpasses that when the sound limb is weight bearing. This elevation can be seen readily in slow-motion videotape analysis, but it may not be as obvious during clinical examination. Observing horses with hindlimb lameness from the front as the horse trots toward you may be useful. This approach allows the pelvic hike to be seen clearly using the horse’s top line as a frame of reference. Subtle pelvic elevation is best seen from this perspective. The use of markers on a fixed part of the pelvis can help to identify asymmetry. Stride length characteristics, height of foot flight, sound, and fetlock drop are also helpful (see following text).

Horses with bilateral hindlimb lameness may have a short, choppy gait that lacks impulsion, but they may have no pelvic hike. Other methods to exacerbate the baseline lameness should be performed, such as circling the horse at a trot in hand or while on a lunge line. Lameness may be accentuated when the lame or lamer limb is on the inside or outside of the circle (see following discussion).

Hindlimb Lameness Confused with Forelimb Lameness

It is important to understand how a horse with unilateral hindlimb lameness modifies its gait so that *hindlimb lameness can mimic forelimb lameness at the trot*. When the lame hindlimb hits the ground, the horse shifts its weight cranially to transfer load away from the lame limb. This causes the head and neck to shift forward and nod down at the same time. The contralateral forelimb bears weight simultaneously with the lame hindlimb and the head nod coincides, thus mimicking lameness in the forelimb ipsilateral to the lame hindlimb. I find it difficult to distinguish clinical characteristics of a head and neck nod caused by forelimb lameness from that caused by ipsilateral hindlimb lameness. Some clinicians have suggested that the head and neck nod caused by ipsilateral hindlimb lameness is less vertical in nature and more forward and downward. Head and neck movement in horses with hindlimb lameness is not always observed. Horses generally must have prominent (>3 out of 5, see later grading discussion) hindlimb lameness before compensatory head and neck movement develops. However, two horses with very similar severity of hindlimb lameness may have different characteristics of movement, which will result in an associated head nod in one, but not in the other. At the pace, a lateral gait, LH lameness mimics RF lameness and RH lameness mimics LF lameness. Evaluation of the horse moving in circles may help to determine if a head nod is related to primary forelimb or hindlimb lameness. If a head nod is exacerbated but a hindlimb lameness is less obvious, then there is probably coexistent forelimb and hindlimb lameness. However if the head nod and hindlimb lameness remain similar or both appear worse, it is more likely that the head nod reflects a primary hindlimb lameness.

Horses can have a head and neck nod at the trot caused by singular forelimb lameness, singular ipsilateral hindlimb lameness, or concurrent forelimb and ipsilateral hindlimb lameness. A prominent head nod is seen in horses with simultaneous LF and LH lameness. The examiner first must determine whether both limbs are affected. Problems arise because occasionally a horse with only LF lameness may shorten the LH stride at the trot, leading the veterinarian to question whether LH lameness also exists. More commonly, however, horses with only lameness in a single forelimb shorten the cranial phase of the stride of the contralateral hindlimb. Horses with only LH lameness can have a rather pronounced head nod, and thus the veterinarian may question the existence of LF lameness. Although a horse with LF lameness may have a compensatory shortened stride of the LH, in the absence of lameness a marked pelvic hike should not be present. A head nod consistent with LF lameness may be inappropriately severe to be caused by mild LH lameness. If a horse has simultaneous LF and LH lameness, it is essential to perform diagnostic analgesia in the hindlimb first, because moderate-to-severe hindlimb lameness produces head and neck nod that is not abolished unless the hindlimb lameness is resolved. Resolution of the pelvic hike and reduction in the head nod should be expected with resolution of the hindlimb lameness.

Simultaneous lameness of a diagonal pair of limbs is less common than simultaneous ipsilateral lameness, except in trotters, because many horses perform at gaits that appear to induce compensatory lameness in the ipsilateral limbs. With simultaneous LH and RF lameness the head nod reflects the forelimb component, a mandatory clinical sign for perception of RF lameness. The horse may drift away from the LH with shortening of the cranial phase of the stride. The horse may have a short, choppy stride in the forelimbs and hindlimbs. The horse may have a rocking gait. It cannot shift weight or compensate from stride to stride in the usual manner and thus tends to rock back and forth from the hindlimbs to the forelimbs.

Reasonable agreement generally exists between clinical recognition of hindlimb lameness and that found experimentally. The use of markers placed on each tuber coxae of 13 horses with unilateral hindlimb lameness showed a consistent increase in vertical displacement of the pelvis during early weight bearing of the lame limb.²³ Although the rise and fall of the pelvis was readily apparent and occurred consistently with weight bearing of the lame and sound limbs, respectively, the absolute height of the pelvis on the lame side did not rise above that of the sound limb.²³ These findings are consistent with my clinical impressions. A head nod down when the diagonal forelimb was bearing weight further confirmed clinical observations that hindlimb lameness can mimic lameness of the ipsilateral forelimb.²³ In a kinematic study using a three-dimensional optoelectronic locomotion system, hip acceleration quotient increased in horses with hindlimb lameness.²⁴ Vertical displacement corresponded to the pelvic hike up on the lame limb, with a simultaneous forward movement of the head and neck during the stance phase of the lame limb.²⁴ Pelvic height differed significantly between sound and lame limbs in an experimental study using a custom-made heart-bar shoe to induce transient hindlimb lameness.²⁵ Pelvic height was reaffirmed as an important indicator of hindlimb lameness, but

exaggerated pelvic hike seen on the lame side was proposed to be caused by push-off from the sound limb and occurred immediately before weight bearing of the lame limb.²⁵ The importance of weight support and asymmetrical dorsoventral hindlimb movement (pelvic hike) was reaffirmed in a study using continuous three-dimensional kinematic monitoring of movement of the tubera coxae.²⁶ The hip (pelvic) hike seen on the lame side was found to be a rapid upward movement that led to an increased dorsoventral displacement.²⁶

GRF has been measured in normal horses and those with forelimb and hindlimb lameness.²⁷⁻³⁰ GRF is reduced in the lame forelimb or hindlimb with compensation by the other limbs. In horses with unilateral forelimb lameness, decreased horizontal GRF in the lame limb is compensated for by increased GRF in the contralateral forelimb and ipsilateral hindlimb.³¹ Decreased vertical GRF in the lame limb is compensated for by increased vertical GRF in the contralateral forelimb during the swing phase of the lame limb, and increased vertical GRF in both the ipsilateral and contralateral hindlimbs during the stance phase of the lame limb.³¹ During unilateral hindlimb lameness the decreased GRF in the lame limb is compensated for by increased GRF in the contralateral hindlimb and the contralateral and ipsilateral forelimbs.³¹ These experimental data support the clinical impression that a lame horse adapts by shifting load to the contralateral limb or by shifting load in a caudal direction for forelimb lameness and in a cranial direction for hindlimb lameness. Kinetic gait analysis in horses with hindlimb lameness or spinal ataxia was recently studied using a force plate mounted in an examination aisle, a setup that may prove useful for clinical use during lameness examination.³² Horses with hindlimb lameness had significant differences from normal and ataxic horses and their own contralateral hindlimbs in vertical peak force, vertical force impulse, and coefficient of variance of vertical force peaks.³² Uniquely, investigators examined ataxic horses at the trot and found significant differences in lateral force peaks (lateral hindlimb movements) between normal horses and those affected with spinal ataxia.³²

Bilaterally Symmetrical Forelimb or Hindlimb Lameness

Bilateral lameness is a common cause of poor performance and may go unrecognized without additional movement, such as circling, lunging, or riding. Horses with bilaterally symmetrical forelimb lameness may have a short, choppy gait when trotted in straight lines. Horses with hindlimb lameness may lack lift to the stride, have a subtle change of balance, or have reduced hindlimb impulsion.⁵ If bilaterally symmetrical lameness is suspected, the veterinarian should select one limb and begin diagnostic analgesia. Horses often show pronounced lameness in the contralateral limb when the source of pain is eliminated.

THE LAMENESS SCORE: QUANTIFICATION OF LAMENESS SEVERITY

I believe it is important to have a standardized lameness scoring system that allows the clinician to quantify

lameness within and between horses. Ideally it should be consistent worldwide, but currently a scale from 0 to 5 generally is used in North America, and a scale from 0 to 10 is often used in Europe. Definitions vary within the grading systems. The system adopted by the American Association of Equine Practitioners (AAEP) provides a framework.³³

- Grade 1 lameness: difficult to observe and not consistently apparent regardless of circumstances (such as weight carrying, circling, inclines, hard surfaces)
- Grade 2 lameness: difficult to observe at a walk or trotting a straight line but is consistently apparent under certain circumstances (such as weight carrying, circling, inclines, hard surfaces)
- Grade 3 lameness: consistently observable at a trot under all circumstances
- Grade 4 lameness: obvious lameness with marked nodding, hitching, or shortened stride
- Grade 5 lameness: characterized by minimal weight bearing in motion or at rest and the inability to move

The AAEP system is potentially confusing because it grades lameness at both the walk and trot. It does not account for a horse that has a shortened stride at walk but trots soundly. In my experience, many lame horses show consistently observable lameness at a trot and therefore would have to be given a score of at least 3, leaving only grades 3 and 4 for use in the majority of lame horses. Horses with bilateral lameness and a shortened stride but no obvious head nod or pelvic hike are difficult to score based on this system.⁵ It does not permit grading under different circumstances, such as straight lines, circles on the soft in each direction, and circles on the hard.⁵

An alternative lameness scoring system is listed in [Box 7-1](#). Lameness is scored only with the horse at a trot, and the grading system is used most often to describe lameness at a trot in hand. The system is useful for both forelimb and hindlimb lameness and is based on a range of 0 (sound)

BOX 7-1

Lameness Scoring

Lameness grades from 0 to 5 are based on observation of the horse at a trot in hand, in a straight line, on a firm or hard surface.

- 0 Sound.
- 1 Mild lameness observed while the horse is trotted in a straight line. When the lame forelimb strikes, a subtle head nod is observed; when the lame hindlimb strikes, a subtle pelvic hike occurs. The head nod and pelvic hike may be inconsistent at times.
- 2 Obvious lameness is observed. The head nod and pelvic hike are seen consistently, and excursion is several centimeters.
- 3 Pronounced head nod and pelvic hike of several centimeters are noted. If the horse has unilateral singular hindlimb lameness, a head and neck nod is seen when the diagonal forelimb strikes the ground (mimicking ipsilateral forelimb lameness).
- 4 Severe lameness with extreme head nod and pelvic hike is present. The horse can still be trotted, however.
- 5 The horse does not bear weight on the limb. If trotted, the horse carries the limb. Horses that are non-weight bearing at the walk or while standing should not be trotted.

to 5 (non-weight bearing). In this system, a horse with unilateral hindlimb lameness of grade 3 or worse would have a head nod that mimics ipsilateral forelimb lameness. This system has limitations because as discussed previously a horse with a moderately severe hindlimb lameness may or may not have an associated head nod, depending on the gait characteristics caused by the source and degree of pain.⁵ There is a practical difference between this scoring system and that put forth by the AAEP. A horse with lameness grade 1 in this modified scoring system would have a lameness grade of 2 to 3 in the AAEP system. The modified scoring system is more flexible and allows clear differentiation among most lameness conditions. However, it does not account for a bilaterally symmetrical gait abnormality and may be difficult to apply in a horse with lameness in more than one limb. Many horses evaluated for subtle lameness or poor performance have a score of 0 to 1 because consistent lameness is not observed. Use of half grades provides greater flexibility and supports adoption of a scoring system from 1 to 10, assuming 0 denotes soundness. A third system is to grade lameness independently at both the walk and trot and under different circumstances—straight lines, circles on the soft, circles on the hard, and ridden—using a relatively simple 9-point scale in which 0 is sound, 2 represents mild lameness, 4 represents moderate lameness, 6 represents severe lameness, and 8 represents non-weight-bearing lameness.⁵ This system takes account of the fact that a horse may appear lamer at the walk than at the trot.

LAMENESS DETECTION

Fetlock Drop

Assessment of fetlock drop, or extension of the metacarpophalangeal and metatarsophalangeal joints, may be helpful in recognition of the lame limb. In general, *the fetlock joint of the sound limb drops farther when this limb is weight bearing than does the fetlock joint of the lame limb*, because the horse is attempting to spare the lame limb by increasing load in the sound limb. This may be easier to detect by video analysis than in a clinical situation and may be more recognizable at the walk than at a trot. However, in some horses with moderate or severe unilateral suspensory desmitis or tendonitis, the fetlock drops markedly on the lame limb when the horse is walking, but at a trot fetlock drop usually is more pronounced in the sound limb. With bilateral suspensory desmitis or severe tendonitis the fetlock may drop further in the lamer limb. In horses with chronic hindlimb suspensory desmitis excessive fetlock excursion on the affected side may falsely reduce pelvic excursion (hike) and make hindlimb lameness less obvious and more difficult to detect.

Use of Sound

Sound can be useful in lameness evaluation. *A lame horse usually lands harder on the sound limb, resulting in a louder noise.* For this sound to be appreciated, the horse must be trotted on a firm or hard surface such as pavement or concrete. However, the sound a horse makes while landing depends greatly on symmetry of the front or hind feet, and the loss of one shoe, different shoe types, or disparity in foot size confounds interpretation. Listening for regularity of rhythm and sound of footfall are important, especially

when evaluating the response of lame horses to diagnostic analgesia, particularly in horses with subtle lameness.⁵

Drifting

Horses with hindlimb lameness generally *drift away from the lame limb*. Drifting is one of the earliest adaptive responses of a horse with unilateral hindlimb lameness, allowing the horse to break over more easily or to reduce load bearing. Drifting may alleviate the need for extensive pelvic excursion (hike). It may make pelvic drop on the lame side more obvious. The horse may mask the lameness by reducing pelvic excursion. In some horses a pelvic hike is undetectable or subtle, but consistent drifting away from the lame side indicates the presence of hindlimb lameness. Many driven STBs with hindlimb lameness drift away from the lame limb or are “on the shaft.” Horses with LH lameness have a tendency to be on the right shaft and vice versa. Drifting away from the lame limb may be most evident when horses have pain from the tarsus distally, although some clinicians have different experiences.⁵ Drifting may result in the horse moving on three tracks.

Horses with severe forelimb lameness also tend to drift away from the lame limb, but this tendency usually is less obvious than in horses with hindlimb lameness. Drifting is most common with carpal lameness when the horse tends to abduct the limb during the swing phase of the stride and appears to push off with the limb, forcing the horse away from the lame side. Abduction seen in horses with carpal lameness should not be confused with swinging the limb or a swinging limb lameness. During protraction abduction seen in horses with carpal region pain appears to involve the horse carrying and placing the limb lateral to the expected site of limb placement. Racehorses with either forelimb or hindlimb lameness tend to drift away from the lame limb while training or racing at speed. This finding is an important piece of the lameness anamnesis.

Drifting toward the lame hindlimb is an unusual but important clinical sign. In horses that drift toward the lame limb, I suspect weakness and lameness exist simultaneously, suggesting a neurological component to the gait abnormality. However, a jumping horse at takeoff may push off more strongly with the nonlame hindlimb and drift across the fence toward the lame limb.⁵

EVALUATION OF LIMB FLIGHT

Observation and characterization of limb flight can be useful in determining the lame limb or limbs and possibly the location of pain within the limb. Abnormal limb flight also may predispose to lameness, especially in horses with faulty conformation. In my opinion, it is impossible to predict the site of pain causing lameness accurately based solely on limb flight and other characteristics, although some abnormalities lead to a high index of suspicion. I believe strongly that the location of pain should always be confirmed by using diagnostic analgesic techniques whenever possible. Some abnormalities are consistently associated with specific lameness conditions, whereas others are general patterns of limb flight seen with many different conditions.

Cranial and Caudal Phases of the Stride

Changes in limb flight in the cranial and caudal phases of the stride can be seen only when the horse is evaluated

from the side. In a normal horse the length of the stride of the paired forelimbs and hindlimbs, measured from hoof imprint to hoof imprint, is nearly identical from side to side. Extension and flexion of the limbs is also similar. From a clinical perspective the length of the stride of the affected limb cranial to the stance position of the contralateral limb is called the *cranial phase* of the stride, and the length of the stride caudal to the stance position of the contralateral limb is called the *caudal phase* of the stride. Obviously in a normal horse these individual parts of the stride are symmetrical. In a lame horse the overall stride length does not appear to change. If stride length changed, the horse could not trot in a straight line. Drifting is associated with lameness and could be explained by a change in stride length, but shorter stride length would be expected in the lame limb, causing the horse to drift toward the lame side, in contrast to the usual observation, drifting away from the lame limb. In racehorses, some of the tendency to drift away or toward the inside of the track could be easily explained by mild differences in stride length or strength (power). However, with the horse at a trot in hand we can assume that total stride length does not change.

In most lame horses the cranial phase of the stride of the affected limb is shortened. The caudal phase is lengthened to maintain a near equal overall stride length side to side. Shortening of the cranial phase of the stride appears to be a learned response of the horse to reduce the time spent during the stance phase and to help during break-over. Loss of propulsion, or an unwillingness to push off with the lame limb, could also explain reduction in the cranial phase of the stride. Because most lame horses have a shortened cranial phase of the stride, this finding, although quite useful in determining in which limb the horse is lame, is not particularly useful in localizing or classifying lameness and is not synonymous with swinging limb lameness. It is also important to recognize that pain causing lameness results in altered proprioceptive responses, to protect the painful area, and these responses may persist for some time after pain has resolved.⁵ A classic example of attenuation of the cranial phase of the stride in the hindlimbs occurs mechanically in horses with fibrotic myopathy. This authentic swinging limb lameness causes a marked abrupt change in the later portion of the protraction phase of the affected hindlimb, shortening the cranial phase and causing a sudden downward and backward action of the limb.

The caudal phase of the stride is lengthened in most lame horses because for overall equal stride length to be maintained, this portion of the stride must compensate. I generally have not found evaluation of the caudal phase of the stride at the trot in hand clinically useful, but it is sometimes a useful observation in horses at a walk (see following text). Some horses with severe palmar foot pain have a shortened caudal phase of the stride at both walk and trot.⁵

Contrast of the cranial and caudal phases of the stride in the lame limb at a walk and a trot is useful. In most horses with forelimb lameness the cranial phase of the stride is slightly shortened at a walk but markedly shortened at a trot. Obviously, in horses with subtle lameness, this clinical sign is absent at the walk and only mildly apparent at the trot. Horses with pain in the dorsal aspect of the foot, such as hoof abscessation or laminitis, may

have a shortened caudal phase of the stride at a walk. This response is an attempt to protect the painful area and to shorten during breakover. These horses walk with a marked camped-out appearance in the forelimbs. At the trot, however, the cranial phase of the stride is likely to be shortened, a clinical contrast useful in localizing lameness to the dorsal aspect of the hoof.

Most horses with hindlimb lameness have a reduction in the cranial phase of the stride at the walk and the trot. Horses with pelvic fractures involving the acetabulum prefer to keep the lame limb ahead of the contralateral limb at the walk and have marked shortening of the caudal phase of the stride, but at the trot the horse has a shortened cranial phase of the stride. Horses with hoof abscessation, most commonly of the dorsal aspect of the hoof, walk similarly, only to trot with a pronounced shortening of the cranial phase of the stride. An explanation for disparity at walk and trot in the phases of the stride in horses with pain at either end of the hindlimb is not readily apparent, but recognition of this phenomena has been quite useful, and consistent. Unilateral or bilateral laminitis and other severe causes of pain in the digit are rare in the hindlimbs and can cause similar clinical signs.

Shortening of the cranial phase of the stride does not always indicate that lameness is present in that limb. At speed a trotter with forelimb lameness shortens the cranial phase of the stride in the ipsilateral hindlimb to avoid interference with the lame limb. This observation sometimes is also made in horses being trotted in hand. This compensatory movement gives the impression that the horse may be lame in the ipsilateral hindlimb, with a subtle pelvic hike. Lameness of the foot and carpus in trotters most often causes this compensatory ipsilateral hindlimb pelvic hike. Once lameness has been abolished in the ipsilateral forelimb, the subtle pelvic hike and shortened cranial phase of the stride in the hindlimb abate. In trotters a shortened cranial phase of the stride and a pelvic hike may be related to faulty weight distribution and interference problems and not to lameness at all.

ABNORMALITIES OF LIMB FLIGHT

Abnormalities of limb flight can cause interference of one limb with another, particularly in trotters and pacers (Figure 7-2). However, horses performing at speed at any gait and those with faulty conformation also are at risk to develop interference injuries. In some horses, interference is of no consequence, but in others, especially trotters, it causes gait deficits. Skin lacerations, bruising, and underlying bone and soft tissue damage (interference injury) may occur. Various boots and other protective devices have been developed to protect the limbs from potential trauma. It is important to assess the presence and location of interference injuries. In some horses, only mild evidence of hitting is found, but other horses may have many painful areas. Chronic interference can be the sole reason for lameness or poor performance.

Front Foot Interference

Front Foot Hitting the Contralateral Forelimb

Horses with toed-out conformation tend to wing in during movement, predisposing to interference injuries.

Fig. 7-2 • Types of interference. **A**, Horses at any gait can be injured by interference of a forelimb with the opposite side. **B**, Interference is common in the trotter and usually involves the ipsilateral forelimb and hindlimb. Interference within a forelimb can be seen in horses that hit the elbow of the same limb. This usually occurs because of high action, excessive weight of the shoes, or a combination of these factors. **C**, Interference in the pacer can involve the forelimb and diagonal hindlimb, commonly called cross-firing. **D**, Forging occurs during trotting when the toe of the hind foot strikes the bottom of the ipsilateral front foot.

Horses with base-narrow conformation or those with a combination of base-narrow and toed-out conformation also are at risk. However, many horses with these conformational abnormalities do not interfere. Some horses walk very closely but widen out at faster gaits. Interference injury from one hind foot hitting the medial side of the contralateral hindlimb occurs infrequently.

All types of horses, especially STB racehorses, are at risk for interference. Interference can involve any level of the limb from the foot to the proximal antebrachium. Mild interference of this type is called *brushing*. STBs often “hit their knees,” which causes swelling, bruising, and lacerations of the skin on the distal medial aspect of the radius. In some horses, large, chronic swellings develop; these consist of mostly fibrous tissue. In others, osteitis of the distal radius or abscessation occurs. Even with protective gear, horses may be reluctant to perform at maximal speed to avoid injury or disruption of gait, or pain caused by interference induces the horse to go off stride.

Interference within the Same Limb

Horses can develop interference injuries within a limb when the hoof or shoe hits the ipsilateral elbow. This type of interference sometimes is seen in trotters with high action (excessive carpal flexion) and is common in gaited horses that perform with heavy shoes intended to cause high action of the forelimbs (see Figure 7-2, *B*).

Front Foot Hitting the Ipsilateral Hindlimb

Interference in trotters usually involves the toe of a forelimb interfering with (hitting) the dorsal aspect of the ipsilateral hindlimb (see Figure 7-2). Various names are

given to the type of interference based on the location in which the injury occurs. Interference injury at the dorsal aspect of the hind foot or coronary band is called *scalping*; in the pastern region it is called *speedy cutting*; in the metatarsal region (shin) it is called *shin-hitting*; and in the dorsal or medial aspect of the tarsus, it is called *hock-hitting*. Because interference is common in trotters, it is important not to overinterpret signs of pain on palpation. Speedy cutting results in pain over the dorsal aspect of the proximal phalanx that should not be misinterpreted as pain associated with a midsubtarsal fracture.

Front Foot Hitting the Contralateral (the Diagonal) Hindlimb

Cross-firing, or the striking of the contralateral (diagonal) hindlimb by the front foot, usually occurs only in pacers (see Figure 7-2, C).

Hind Foot Interference

Interference as a result of a hind foot hitting the foot of the ipsilateral forelimb (*forging*) is common and usually does not result in injury. Many horses forge at a trot in hand or while being ridden. In horses with shoes the sound is unavoidable but may not be a sign of a pathological condition. Forging is most common in horses that are trotted in deep footing. Forging may reflect imbalance, lack of strength, incoordination, or poor foot trimming.⁵

Forelimb: Common Abnormalities of Limb Flight

Winging In and Winging Out

Common limb flights observed during lameness examination include winging in and winging out movement of the front feet and are often related to conformation (see Figure 4-13). Horses that are toed out tend to wing in, whereas those that are toed in tend to wing out. Such abnormalities do not necessarily compromise performance. However, such movement may result in uneven loading of the soft tissue structures and uneven hoof wear, leading to chronic imbalance. Horses that wing in tend to develop interference injuries and wear the medial aspect of the shoe excessively. Horses that wing out tend to develop lateral branch suspensory desmitis and wear the lateral aspect of the shoe excessively.

Lateral Placement of the Foot during Advancement (Abduction)

Horses normally advance the forelimbs straight ahead. When advancing the limb, horses with articular carpal pain, and some horses with pain in the proximal metacarpal region, place the foot lateral to the expected foot position. This action has been described as *abduction* of the limb, but this term may infer swinging the limb, and horses with carpal lameness seem to place the limb laterally rather than swinging the limb. However, ankylosis associated with severe osteoarthritis or arthrodiesis of the carpus does necessitate swinging the limb during advancement, a much different movement from that seen in horses with more mild carpal region pain.

Horses with this abnormality of flight almost always have a shortened cranial phase of the stride. They tend to push off with the affected limb from the lateral location, resulting in a wide or peg leg type of motion at walk, and sometimes at trot. With bilateral carpal lameness the horse appears to move widely bilaterally. Not all horses with

carpal pain move widely, and this gait change is seen more often in horses with middle carpal or carpometacarpal joint pain than in those with pain in the antebrachioacarpal joint. Some horses with upper limb lameness may carry the limb widely while walking, although this characteristic is not typical of horses with shoulder pain. A horse with a humeral stress fracture sometimes may travel widely, similar to a horse with carpal lameness, but the latter is more likely. A horse with pain in the lateral aspect of a foot may move widely in the affected limb to reduce load laterally. This characteristic is seen in STB and TB racehorses with subchondral bone trauma or early stress fractures of the distal phalanx.

Plaiting

The verb *to plait* means to braid or pleat, or to make something by braiding.³ The term is used to describe horses that walk or trot by placing one foot directly ahead of the other foot. Plaiting in the forelimbs is not nearly as common as in the hindlimbs and usually is the result of base-narrow, toed-out conformation. Old horses (usually broodmares) with severe carpus osteoarthritis and carpus varus limb deformities occasionally may swing the limb laterally and place the foot far enough medially to end up in front of, or lateral to, the opposite foot. Some horses with shoulder region lameness guard the limb and travel very closely in front. Plaiting in the forelimbs can be seen in horses with recent fractures of the thoracic dorsal spinous processes at the withers.⁵ Horses with neurological disease occasionally plait.

Limb Flight in Horses with Shoulder Region Lameness

I include this section principally because the shoulder often is erroneously incriminated as the source of pain. Horses with moderate-to-severe lameness of the scapulo-humeral joint or bicipital bursa have a marked shortening of the cranial phase of the stride. They also have an unusual motion of the shoulder joint that is difficult to describe. Because the cranial phase of the stride is shortened, during breakover the affected shoulder joint seems to drop or buckle forward, more so than the opposite side (assuming lameness is unilateral). There may be prominent lifting of the head and neck. Limb flight is either straight ahead or somewhat close to the opposite forelimb. Horses with shoulder region pain *do not consistently* travel widely, or abduct the affected limb. However, racehorses with humeral stress fractures may occasionally travel widely in front. With mild lameness there are no typical gait characteristics.

Hindlimb: Common Abnormalities of Limb Flight

Stabbing or “Stabby” Hindlimb Gait

A common abnormality of limb flight seen in horses with hindlimb lameness is described as a *stabbing* or “*stabby*” gait. During protraction of the lame hindlimb or hindlimbs, the limb travels medially, close to the opposite hindlimb, and then moves laterally during the later portion of the swing phase and is placed lateral to the expected foot placement. This motion results in excessive wear of the lateral or dorsolateral aspects of the shoe. Although this gait often is seen in horses with distal hock joint pain, it can be seen with many other sites of pain from the distal tibia to the

foot. Therefore diagnostic analgesia is required to localize the pain. However, horses with the most marked shoe wear consistent with this abnormality of limb flight are most likely to have tarsal lameness. Exaggerated stabbing hindlimb motion often is seen in horses with neurological disease.

Abduction of the Hindlimbs during Advancement

In some horses with hindlimb lameness the limb is carried forward in a position lateral to the expected position (i.e., abducted). In some horses with this limb flight the limb swings outside the expected line of limb flight, only to strike the ground near the expected position. Lateral swinging of the limb begins immediately after the lame limb leaves the ground. I have observed this abnormality most consistently in horses with stifle lameness, but it also occurs with some other upper limb lameness conditions. Care must be taken when evaluating horses that normally travel widely behind, such as trotters.

I have recognized lateral swinging of the hindlimb most commonly in pacers with articular lesions of the stifle, because the normal gait in these horses is to swing the hindlimb more than would be expected from other horses. Many horses with stifle lameness carry the limb forward lateral to the expected position, but just before impact may actually stab laterally. Therefore the veterinarian must pay close attention to limb flight directly after the lame limb leaves the ground and while it is passing the contralateral limb. Another common characteristic of horses with stifle lameness is a shortened cranial phase of the stride. The stifle joint also may appear unusually prominent and be carried somewhat away from the flank and slightly externally rotated.

Plaiting

Plaiting is more common in the hindlimb than in the forelimb and usually results from lameness rather than faulty conformation, although plaiting can occur in a horse with severe base-narrow conformation. Plaiting can be seen in horses with unilateral or bilateral lameness. In horses with unilateral lameness, it appears that limb flight actually may be altered in both hindlimbs, resulting in both hind feet being placed ahead, or in some horses, lateral to the opposite foot. In horses with severe hindlimb lameness, it appears that the affected foot is being swung around and placed directly in front or lateral to the unaffected foot. Alternatively, the horse may be trying to support most of its weight on the unaffected limb and moves this limb inside to support the lame side. In horses with bilateral lameness, it is equally difficult to determine what exactly is causing the plaiting. The horse may be reluctant to bring either hindlimb along the expected line of flight, leaving the limb medially and forcing the opposite limb to the outside to avoid interference. A horse may swing each hindlimb around the other, ultimately ending placing one foot ahead or lateral to the other. An unusual rocking type of gait is observed in horses with bilateral hindlimb lameness and plaiting. I have observed plaiting most commonly in horses with osteoarthritis of the coxo-femoral joint or pelvic fractures, but I also have seen it in horses with bilateral distal hock joint pain or suspensory desmitis. Plaiting also is observed in some horses with sacroiliac joint pain.⁵

Mechanical Lameness of the Hindlimb and Limb Flight

Mechanical conditions of the hindlimb can cause profound abnormalities of limb flight (see Chapter 48). These are termed *lameness conditions* because of the gait abnormality exhibited, although in many horses pain is not characteristic.

Stringhalt

Stringhalt, an ill-defined neuromuscular disorder of the hindlimb, causes mild-to-severe hyperflexion of the tarsus. The condition can be unilateral or bilateral and usually is most obvious at a walk but can also be seen at the trot. In horses with severe stringhalt the dorsal aspect of the hoof comes close to or hits the ventral aspect of the abdomen. Horses may exhibit the clinical signs more prominently during backing or when initially moved after previous standing.

Fibrotic Myopathy

Fibrotic myopathy is characterized by a sudden downward and backward motion of the limb (slapping motion) that occurs during, and restricts the length of, the cranial phase of the stride. Hyperflexion of the hock is not a clinical feature of this gait deficit, but the restriction of the cranial phase of the stride and the slapping motion and sound can be confused with the clinical signs of stringhalt. It is most obvious at a walk.

Upward Fixation of the Patella

Upward fixation of the patella is a classic hindlimb gait deficit and one that displays the function of the stay or reciprocal apparatus. It can be intermittent or permanent and unilateral or bilateral. When the patella is locked in position over the medial trochlear ridge of the femur, the stifle and hock joints are held in extension, whereas the digit is held in partial flexion.

Shivers

Shivers is an ill-defined neuromuscular disease and is most common in Warmbloods and draft breeds; it can occur unilaterally or bilaterally. Clinical signs usually are most obvious when a horse is backed or first moves from the stall. Horses elevate and abduct the limb, and the limb may actually shiver or shake. The tail often is elevated. Signs may be accentuated if the horse is tense.

Other Hindlimb Gait Deficits

Other unusual unexplained gait deficits affecting one or both hindlimbs are observed occasionally, and they often have characteristics similar to those seen with stringhalt, fibrotic myopathy, upward fixation of the patella, and shivers. However, some distinction usually prevents easy recognition and diagnosis. A gait deficit characterized by marked hindlimb abduction seen most prominently at the walk has been recognized. This is most similar to fibrotic myopathy, because a consistent abduction of the limb is observed, and signs tend to abate when the horse is trotted. It may be related to scarring, abnormal function of the biceps femoris and gluteal muscles, or neurological disease.

Neurological disease can cause many different gait deficits, most commonly recognized in the hindlimbs but also in forelimbs. A complete neurological evaluation usually is

not performed during lameness examination unless certain abnormalities are observed. Abnormal or excessive circumduction of the hindlimbs, a bouncy, stabby hindlimb gait noticed when the horse is trotted, knuckling over behind or crouching, stumbling, and lethargy are signs that should prompt further investigation.

EVALUATION OF FOOT PLACEMENT

It is important to critically evaluate foot placement. Ideally, both the front and hind feet should land flat and level on a firm surface. Foot strike patterns change on soft footing. Evaluation of foot strike is most important in horses with lameness localized to the foot, but it can also give clues regarding other causes of lameness. Abnormal foot placement can be the result of a current lameness problem but may also cause lameness.

In the forelimbs, horses commonly land on the lateral side of the foot first before rocking medially. This can be the result of abnormal conformation or hoof imbalance and can predispose to lameness in the digit and suspensory branch desmitis. Landing abnormalities in the dorsal-to-palmar direction are common but are difficult to recognize unless severe. Horses with profound pain in the toe caused by laminitis or hoof abscessation land heel first, giving a camped-out appearance, and have a shortened caudal phase of the stride. Horses with palmar foot pain may compensate by landing toe first, causing abnormal stress on the dorsal structures of the foot, but this characteristic is difficult to see except in slow motion.

In the hindlimbs, several patterns of abnormal landing or motion are recognized, not all of which are a cause or result of lameness. Landing on the toe is commonly considered the result of heel pain, but many horses with severe hindlimb lameness land on the toe. This tendency is particularly prominent when the horse is first moved, and most horses warm out of the lameness. Horses may land on the toe when walking up an incline or at the walk on the flat but generally place the heel on the ground when trotted. The most consistent lameness I see in horses that land on the toe is distal hock joint pain, but any cause of lameness from the tarsus to the foot can cause a horse to exhibit this abnormal landing pattern. Horses with lameness of the metatarsophalangeal joint region, including osteoarthritis, tenosynovitis of the digital flexor tendon sheath, or desmitis of the accessory ligament of the deep digital flexor tendon have a tendency to land on the toe. Horses with adhesions within the digital flexor tendon sheath may have severe mechanical restriction that causes toe-first landing. Old Western performance horses with deep digital flexor tendonitis have severe toe-first landing and may stand on the toe and even rise up in the heels during the examination. The condition can be bilateral or unilateral and is difficult to manage. Mild or moderate tendency to land on the toe also has been attributed to stifle lameness.⁵

Abnormal movement of the lower or entire hindlimb occasionally is noted when horses are watched from behind. Horses may place one or both hind feet in an axial position and collapse or break over the lateral aspect of the fetlock region.⁵ Another uncommon hindlimb motion is characterized by excessive rotation of the hindlimb. The horse plants the hind foot and rotates the heel laterally, causing abnormal loading or twisting of the distal limb.⁵

Although this movement can lead to lameness, it sometimes is seen in horses that are successful in various sporting endeavors. I have seen this type of hindlimb motion most often in TB racehorses.

ADDITIONAL MOVEMENT DURING LAMENESS EXAMINATION

Further information about the character of lameness often can be obtained by observing the horse as it moves in circles and is ridden or driven. Some lameness conditions are apparent only under these circumstances.

Hard and Soft Surfaces

Comparison of movement on hard and soft surfaces is valuable. Foot lameness usually is worse when the horse is trotted on hard surfaces and better on a soft surface, such as grass or sand. Horses with suspensory desmitis or digital flexor tendonitis are more likely to show lameness on a soft surface. Deep sand may accentuate some lameness conditions, but an extended lameness examination under these conditions could cause proximal suspensory desmitis.⁵ A slight downward incline or an uneven, rough surface may make subtle lameness more apparent.⁵

Circling

Lameness often is much more pronounced when a horse is circled. Horses should be circled in both directions: to the left (counterclockwise, LF and LH on the inside) and to the right (clockwise, RF and RH on the inside). Lameness may be more pronounced when circling at either the walk or the trot. In some horses with incomplete fractures, baseline lameness at a trot in straight lines in hand may be subtle or absent. Lameness may be readily apparent during circling, even at the walk. The additional forces of torsion and bending during circling are added to those of compression and tension. In horses with incomplete fractures, such as those involving the proximal or distal phalanges, torsion or bending forces during circling likely cause mild separation of the fracture fragments and exacerbate lameness. In horses with other lameness conditions, exacerbation of lameness may be caused by a change of load on the affected soft tissue structure or bone, redistribution of the forces of compression and tension in a medial-to-lateral direction, or additional forces of bending and torsion.

From a clinical perspective the force of compression may be dominant to other forces in determining a horse's response to circling, but it is not the only factor. Extension of the limb is also influential.⁵ When the lesion is in the outside limb while the horse is circling and undergoing compression, exacerbation of the lameness occurs. For instance, lameness in horses with medially located lesions of the distal phalanx or of the third carpal bone is worse when the limb is on the outside of the circle and the lesion is being compressed. For some soft tissue injuries, tension forces may be more important. Lameness in horses with proximal suspensory desmitis often is worse with the limb on the outside of the circle, suggesting that tension is important in the expression of lameness. The same observation is not seen in horses with more distally located suspensory desmitis.

Is the lameness seen in a horse that is moving in a circle the same lameness that is seen while the horse is walking or

trotting in straight lines? In most instances, circling exacerbates the primary lameness seen in straight lines. If lameness is subtle or nonexistent when the horse is evaluated in a straight line, the lameness seen during circling becomes the baseline lameness. The clinician must recreate the same conditions of circling when evaluating the results of diagnostic analgesic techniques. There is always the possibility that lameness seen during circling may be different from the baseline lameness seen in straight lines. For example, a horse has grade 1 RF baseline lameness when it moves in a straight line that increases to grade 3 when trotted in a circle to the left, but still has grade 1 lameness when trotted to the right. Lameness in a straight line and when trotting to the right is absent after palmar digital analgesia but still is rated grade 3 when the limb is on the outside of the circle. This horse has two problems in the RF: palmar foot pain and an additional carpal lameness that becomes evident when the horse is trotted to the left (RF on the outside of the circle). With bilateral forelimb or hindlimb lameness, primary lameness often is seen in a single limb in straight lines, but during circling the lameness is seen in whichever limb is on the inside (or outside) of the circle. Circling is useful in exacerbating the primary lameness problem and identifying an additional cause of lameness not previously noted. This additional lameness must be recognized and treated separately from the baseline lameness.

Good correlation usually exists between the cause of lameness seen on the straight and that seen while circling the horse; thus it is helpful to circle the horse to try to exacerbate lameness. Circling can be done at the walk and trot in hand and while lunging or riding the horse. Horses often move more freely and naturally when lunged than when being led.⁵ However, lunging is not possible in some horses, particularly racehorses, and circling while being led is better than no circling. The surface should be nonslip because horses may be hesitant to move freely on slippery surfaces and shorten or alter the stride even when lameness is not present.⁵ Soft footing is best when the horse is first being lunged, because the horse can buck and play without risk of injury. Hard or firm surfaces are best to exacerbate many lameness conditions, but the surface must be nonslip to avoid possible injury.

That lameness of the upper forelimb or hindlimb is worse when the limb is on the outside of the circle is a common misconception. This is true in some horses, but a generalization cannot be made (see following text). Shortening of the cranial phase of the stride may appear more obvious with the limb on the outside of the circle, but exacerbation of lameness judged by the degree of head nod may not be observed. Another misconception is that horses with lameness of the foot are lamest when the limb is on the inside of the circle. Although a majority (65%) of those with lameness localized to the foot are lamest when the limb is on the inside of a circle, lameness can be worst with the lame limb on the outside of a circle. This depends in part on the location of pain within the foot.

Forelimb

Lameness Worsened with Limb on the Inside of the Circle

In many horses, lameness originating from the fetlock region to the foot is worse with the affected limb on the inside of the circle. Comparison of circling on hard and soft surfaces is useful. Baseline lameness associated with

foot pain usually is dramatically increased when the horse is circling on a hard surface, but a less obvious response is seen when circling on softer surfaces. However, lameness in horses with medially located lesions can be worse with the limb on the outside of the circle.

Horses with lameness of the metacarpal region vary in response to circling. Lameness related to metacarpal bony injury and distally located lesions in the suspensory ligament or digital flexor tendons tends to be worse with the limb on the inside of the circle, whereas lameness in those with proximal suspensory desmitis is worse with the limb on the outside. Horses with suspensory branch desmitis may show a different response depending on lesion severity and whether the injured branch is undergoing tension or compression.

In my experience, the degree of lameness in horses with pain originating from the forearm, elbow joint, arm, and shoulder joint region tends to be worse with the limb on the inside of the circle, but opinions and experiences do vary.⁵ Observations may differ if horses are examined while led in hand as opposed to being lunged or ridden. Lameness in some horses with mechanical restriction of movement that dramatically decreases the cranial phase of the stride may be worse with the limb on the outside of the circle.

Lameness Worsened with Limb on the Outside of the Circle

Horses with medially located lesions of the lower limb, especially foot lameness, proximal metacarpal lesions (proximal suspensory desmitis or avulsion injury to the McIII at the suspensory origin), or carpal pain often are more lame with the limb on the outside of the circle. Horses with lesions in the antebrachiocondylar joint are less consistent in response to circling compared with those with middle carpal joint lesions, because most of the common injuries involve the medial aspect of the latter. Upper limb lameness is accentuated in some horses.⁵

Lameness Improved When Circling

Lameness that appears better on a circle than in straight lines is uncommon. Lameness in horses with medially located lesions in the foot or carpus may improve when the limb is on the inside of a circle. Baseline lameness in horses with middle carpal disease involving the third and radial carpal bones improves with the limb on the inside of the circle. A STB racehorse with grade 2 or 3 RF baseline lameness in a straight line that increases to grade 3 or 4 when circled to the left, but is only grade 1 or 2 when circled to the right, may have lameness associated with the middle carpal joint, but pain in the medial aspect of the foot also is possible.

A horse with bilateral forelimb lameness (e.g., a horse with grade 3 RF baseline lameness in straight lines) may show grade 3 to 4 RF lameness when trotting to the right but grade 1 LF lameness when trotting to the left. The primary lameness is in the RF, and lameness is worse when the limb is on the inside of the circle. Circling to the left induced lameness in the LF, masking the RF lameness, because bilateral lameness existed that was not recognized when the horse was trotting in a straight line.

Hindlimb Lameness and Circling

In my experience, baseline lameness in most horses with any hindlimb lameness is worse when the limb is on the

inside of the circle. Exceptions do exist, and some have different experiences and thus opinions.⁵ Lameness associated with proximal suspensory desmitis often is worse with the affected limb on the outside of the circle, and the horse may stumble or take bad steps. Lameness in some horses with stifle lameness appears worse with the affected limb on the outside of a circle, but in others it appears similar to the left and the right. Many conditions of the stifle involve the medial femorotibial joint, a location that would be compressed with the limb on the outside. Lameness in any horse with a medially located lesion involving the distal hindlimb could be worse with the limb on the outside of the circle. Circling may be useful in exacerbating a primary lameness but generally is not helpful in localizing pain causing lameness.

Observation during Riding

Lameness may not be apparent when the horse is evaluated in hand in straight lines and circles but is obvious when the horse is ridden. This lameness becomes the baseline lameness for further investigation. The additional weight of a rider can exacerbate both forelimb and hindlimb lameness. Gait abnormalities and performance in horses with primary back pain or those with substantial muscle pain secondary to hindlimb lameness usually are worse when they are ridden. Hindlimb gait restriction can occur in horses with back pain but may be apparent only when a horse is ridden.⁵ Problems related to an ill-fitting saddle or girth, behavioral problems, head shaking, abnormal posture or carriage of the head and neck, and refusal to take a lead or bend in certain directions may be evident only when a horse is ridden.

A horse may be easier to control when ridden than when in hand or on the lunge. Performance of specific maneuvers by the horse may accentuate lameness. A collected trot that forces more weight onto the hindlimbs may exacerbate hindlimb lameness. An extended trot may reveal the horse's inability to extend one limb compared with another and reveal lameness that was completely imperceptible under all other circumstances. The primary complaint, such as poor-quality flying changes of lead at canter, may require a riding assessment regardless of whether baseline lameness is evident under other circumstances.

However, it is important for the veterinarian to separate his or her observations from those perceived by the rider. Identification of the lame limb may be difficult for a rider, although he or she may have a very strong opinion. If the veterinarian's observations differ, the rider may be difficult to convince. It is also essential to recognize that bad riding can actually induce a false lameness that is completely unapparent if the horse is ridden well. Nonetheless, an experienced rider, trainer, or driver can be quite helpful in assessing the horse's response to diagnostic analgesia or therapy, particularly in horses with thoracolumbar pain, subtle hindlimb lameness manifested only when ridden, and poor performance related to a musculoskeletal problem. Working regularly with a skilled, experienced, and reliable rider can be very helpful.

Subtle differences in weight distribution of the rider may exacerbate or mask the presence of forelimb and especially hindlimb lameness. When the horse is performing the posting (rising) trot, lameness may be more or less

prominent depending on which diagonal the rider is using. In the rising trot the rider sits on either the left or right diagonal. On the left diagonal the rider is sitting when the LF and RH are bearing weight and rising during the swing phase of these limbs. On the right diagonal the rider is sitting when the RF and LH are bearing weight. The correct diagonal is the outside diagonal (i.e., left diagonal on the right [clockwise] rein). Hindlimb lameness often is worse when the rider sits on the diagonal of the lame limb.⁵ Therefore if the horse is lame in the RH, the lameness appears and feels worse when the rider sits on the left diagonal. Horses with hindlimb lameness may try to force or throw the rider to sit on the more comfortable (for both horse and rider) diagonal.⁵ A horse with bilateral hindlimb lameness may appear lame in the RH when the rider sits on the left diagonal and lame in the LH when the rider sits on the right diagonal.⁵ Forelimb lameness is influenced less by the diagonal on which the rider sits, but a similar pattern exists. RF lameness is worse with the rider sitting on the right diagonal.⁵ This difference in lameness expression may be perceptible only by an experienced rider. Mild hindlimb lameness may become most obvious when a horse is ridden in small figure eights (two 10-m-diameter circles linked), especially when the horse changes direction from left to right or from right to left.

Observation of Inclines

Walking or trotting a horse uphill or downhill may exacerbate lameness or identify previously unapparent lameness. Lameness in horses with suspensory desmitis may be worse when they walk uphill or downhill. Lameness associated with palmar foot pain may be worse when the horse walks downhill, and the horse may show a tendency to stumble. Horses that tend to stumble or knuckle behind while walking downhill may have loose stifles (inability to maintain the position of the patella, usually caused by lack of muscle tone). Horses with neurological disease usually show more pronounced clinical signs when walking uphill or downhill.

A superficially flat, hard surface may actually slope; this can influence lameness because the horse's feet will be tilted with one side lower than the other. Thus the horse may appear different when trotting away from the observer than when returning.

EVALUATION OF LAMENESS WITH A TREADMILL OR GAIT ANALYSIS

The use of a treadmill for poor performance evaluation is well recognized, and its use in lameness assessment is discussed in detail in Chapter 98. The clinical relevance of lameness apparent only on a treadmill is open to debate. I do not find lameness examinations on a treadmill at high speed particularly useful unless slow-motion videotape is available. I prefer to assess the horse while training or performing. A horse may modify its normal gait on a treadmill. Good correlation was demonstrated between gait regularity in horses exercised on a track and a treadmill, but treadmill strides and steps were shorter, and the swing phase of the stride was reduced.³⁴ Horses require at least

two training sessions on a treadmill before the gait becomes consistent.³⁵ Stride characteristics of horses galloping on a treadmill change as the slope of the treadmill increases from 0% to 8%; horses reduced the suspension phase to maintain overall stride length.³⁶

Gait analysis is discussed in Chapter 22. To date in the clinical setting, assessment by an experienced, skilled observer has been more reliable in the identification of the lame limb or limbs than other, more sophisticated methods of gait analysis.

Chapter 8

Manipulation

Mike W. Ross

Flexion or other manipulative tests often are used to induce or exacerbate lameness during lameness or prepurchase examinations.

INDUCED AND BASELINE LAMENESS

It is important to understand the concept of *induced lameness* and the possible difference between lameness seen at this stage and baseline lameness. During lameness examination, baseline lameness is established before any form of manipulation is performed. This may be difficult if more than one limb is involved, if lameness is subtle or subclinical, or if lameness is bilaterally symmetrical, which causes a gait abnormality without overt lameness. Lameness provocation is performed to exacerbate the baseline lameness or to provoke a hidden gait abnormality and attempt to localize the source of pain within a limb or limbs.

Provocative tests create induced lameness that may not have any clinical relevance to the baseline lameness observed during initial movement. These tests are not sensitive or specific and often result in false-positive and false-negative findings. Many horses with palmar foot pain respond positively to the “fetlock flexion test” (or lower limb flexion test, see following text) and could erroneously be thought to have lameness of the metacarpophalangeal joint. Similarly, a horse with proximal suspensory desmitis (PSD) may show exacerbation of lameness after distal limb flexion. A racehorse with baseline lameness as the result of a carpal chip fracture may have preexisting low-grade osteoarthritis of the metacarpophalangeal joint and respond positively to lower limb flexion but response to carpal flexion may be equivocal. Diagnostic analgesia is essential to localize the source or sources of pain. In the hindlimb, hock flexion, the so-called “spavin test,” causes many false-positive reactions.

FLEXION TESTS

Flexion tests were first described early in the twentieth century, but information regarding the degree of flexion, force, or duration of the tests was lacking.¹ Variations in technique persist and produce variable responses that can be misleading. There appear to be more false-positive reactions to flexion than there are false negatives, but the

latter do occur. Flexion tests are useful during prepurchase examinations because the horses being examined usually are relatively sound, and the tests are useful at uncovering hidden sources of pain. Flexion tests may be useful in exacerbating lameness, particularly when the primary or baseline lameness is in the region being flexed, but sensitivity is doubtful. Horses judged to be clinically sound underwent a “normal” and then a “firm” lower limb flexion test (fetlock flexion).² Of the 50 horses tested, 20 had a positive response to normal flexion, and 10 of these horses were judged to be lame while trotting for about 15 m (50 feet) or more. Forty-nine of 50 horses had a positive response to firm flexion, and 35 of these remained lame for a minimum of 15 m. In this study the force applied was not calibrated, 7 of the 50 horses developed lameness within 60 days of completion of the study, and 24 horses had radiological abnormalities that could have contributed to a positive response to flexion.² Although there may be an explanation for a positive response in some horses, the high percentage of positive results in the study is in agreement with my clinical impression. In a study using the Flextest (Krypton Electronic Engineering NV, Leuven, Belgium), an apparatus designed to control traction force and time during a lower limb flexion test, the optimal force and time for flexion were 100 N and 1 minute, respectively. There was a positive response to flexion in many horses that were considered sound, and a positive response in sound horses was more likely in those in active work than in horses that had been rested or turned out on pasture. Horses were more likely to manifest a positive response to flexion as the force used in the test was increased.³ A false-positive response to flexion can be observed in clinically normal horses and in those with unimportant low-grade problems. Lameness induced by flexion in these horses may have little clinical relevance.

However, other evidence suggests that a positive response to lower limb flexion in sound horses may be useful to predict future lameness. In a retrospective study, 151 initially sound horses were followed for 6 months. Twenty-one percent of horses with a positive forelimb flexion test result developed lameness in the area being flexed, whereas only 5% of horses with a negative flexion test result subsequently developed lameness. In young Swedish Warmbloods there was a positive correlation between a positive response to flexion and a subsequent insurance claim related to lameness.⁴

In a more recent study the predictive value of the lower limb flexion test was debated.⁵ Sixty percent of sound horses responded positively to the flexion test. There was no influence of body weight, height, or range of motion, but outcome of the flexion test increased significantly with age and in mares. Over a 6-month period the number of horses responding positively decreased significantly, a

finding that casts doubt on the possible predictive value of the test.⁵

Flexion tests lack specificity because it is nearly impossible to flex a single joint without flexing other joints or nearby tissues, particularly in any hindlimb or distal forelimb flexion tests. Elevation of a limb without flexion in severely lame horses may exacerbate the baseline lameness, because horses guard the limb or need to warm out of the lameness for a number of steps while trotting, thus complicating interpretation. Hindlimb flexion tests are less specific than forelimb tests because the reciprocal apparatus prevents flexion of any joint without concomitant flexion of other joints. Hindlimb flexion tests are useful in exacerbating baseline lameness, but positive responses to individual lower limb and upper limb tests, in my opinion, only localize pain causing lameness to the entire hindlimb. I believe that flexion tests are useful in exacerbating lameness, and in some horses it is the baseline or relevant lameness that is being worsened. In general, unless the horse's response is clearly pronounced and different from that of other manipulation, lameness cannot be localized based on response to flexion alone. Diagnostic analgesia should always be used, when possible, to localize pain.

Order, Duration, Force, and Venue during Flexion Tests

Consistency in technique is essential. Although force exerted by individuals varies, the flexion technique of experienced practitioners is sufficient to objectively assess response to flexion.⁶ Response to flexion can and should be compared with response in the contralateral limb. Ideally the flexion test should be performed in the contralateral sound limb first before being performed in the suspect limb, to determine the horse's response. Accurate assessment of response to flexion in the contralateral nonlame limb may not be possible if the horse is severely lame after flexion of the lame limb and lameness persists. In some instances, baseline lameness is actually increased by forcing the horse to stand for the contralateral flexion test, a useful observation seen most commonly in horses with forelimb lameness (see following text). Horses with nearly bilaterally symmetrical lameness may have a similar positive test result in the less-lame contralateral limb.

Duration of flexion is somewhat controversial and may be an individual choice. In a study evaluating lower limb flexion, duration of 1 minute was considered ideal, because normal horses that underwent flexion at 100 N for 1 minute had few false-positive responses.³ Maintaining firm flexion for 1 minute while performing all flexion tests and repeating the tests in the contralateral limbs can make this portion of the lameness examination time-consuming. On the other hand, if the clinician takes the time to perform these tests, optimum chances of success are improved. A false-positive result is more useful than a false-negative test result. Some clinicians prefer to perform flexion tests with more force but for a shorter duration. This technique works well for lower limb flexion tests. Seldom is it possible to maintain some upper limb manipulative procedures for 1 minute. Thus some latitude is necessary. I believe that duration of flexion of 45 seconds to 1 minute is enough to elicit an accurate response in most horses.

Force used during flexion varies considerably, but excessive force induces lameness in most normal horses.

Forces in the range of 100 to 150 N represent a moderate degree of force for lower limb flexion tests. In studies using a dynamometer, the maximum amount of force that could be used without a consistent withdrawal response in normal horses was 150 N.⁷ The amount of force also depends on the size of the horse or the joint being flexed. The amount of force used in adult horses cannot be used in foals. Horses with obvious osteoarthritis or articular fracture, or those with substantial soft tissue injury likely to be affected by the flexion test, do not tolerate the same force as horses with more mild conditions. In a study of healthy and injured Thoroughbred (TB) racehorses, a positive correlation existed between decreased range of motion and joint injury.⁸ Loss of joint motion was most likely caused by joint capsule fibrosis, but pain associated with increased intraarticular pressure from effusion or flexion also may have limited joint motion.⁸ I recommend flexing a joint as much as possible with an amount of force just slightly less than the force that consistently causes a withdrawal response. Consistency should be applied between horses, paying attention to how the horse reacts; obvious resistance to sustained passive flexion may be clinically significant.

Proper evaluation of the results of flexion tests requires that the horse be observed while trotting in a straight line on a firm, nonslip surface. Evaluation during trotting is important to differentiate those horses resistant to static flexion from those with an authentic positive flexion test result. Horses usually are trotted in hand, although occasionally a horse's response to flexion is evaluated while it is being ridden. The horse should be trotted immediately after the limb is placed to the ground, with care taken to avoid scaring the horse or providing any excessive encouragement to trot, because many horses will slip initially, gallop off, or balk, all of which necessitate test repetition. If possible, the horse should be trotted away from the examiner for a minimum of 12 to 15 m.

Causes of Pain during Flexion and Positive Flexion Test Results

Forced flexion of a joint can induce pain in many potential sites. Force is being applied to both articular structures and surrounding soft tissues. The tissues on the flexion side of the joint are being compressed, whereas tissues on the extension side are under tension. During flexion, intraarticular pressure and intraosseous pressure in subchondral bone are increased.^{3,8} Stretching or compression of the joint capsule, vascular constriction, and activation of pain receptors in the joints and surrounding soft tissues also can occur during flexion.³ It is rarely possible to attribute pain on static flexion or during movement after flexion to an individual articular surface. The "fetlock flexion test" is a misnomer because as it is commonly performed it includes the interphalangeal joints and stresses surrounding soft tissue. Thus the names *lower limb flexion test* or *fetlock region flexion test* are more appropriate.

Positive Responses to Flexion

Positive responses to flexion can be seen with static flexion (see Chapter 6) and when movement follows flexion. A positive flexion test result is defined as obvious lameness or an increase over baseline lameness that is observed for more than three to five strides while the horse trots in a straight line after flexion. A mild response, even in sound

horses, often is seen in the first few strides, a finding that should be compared with the contralateral limb. Sound horses warm out of this mild response quickly. Of 100 sound horses 50% had a slight response, 35% had mild lameness and 15% had distinct lameness after a lower limb flexion test.⁵ A persistent, one- to two-grade increase over baseline lameness for several steps is a positive response. In horses with hindlimb lameness a marked positive response often is accompanied by reluctance to place the heel on the ground, and the horse may land only on the toe for several strides.

Forelimb Flexion Tests

Lower Limb Flexion Test

The lower limb flexion test often has been equated erroneously with the fetlock flexion test. The fetlock region can be flexed independently of interphalangeal joints (see following text). The lower limb flexion test is the most common test performed in the forelimb and involves placing a hand on the toe and forcing the fetlock and both interphalangeal joints into firm flexion (Figure 8-1). A positive response to flexion can be observed with any condition of the distal interphalangeal, proximal interphalangeal, and metacarpophalangeal joints or the navicular bone or bursa; other causes of palmar foot pain; digital flexor tenosynovitis; any soft tissue problem in the palmar pastern region; and lameness associated with the branches or proximal aspect of the suspensory ligament (SL) or proximal sesamoid bones (PSBs). Horses with lesions of the PSBs usually have markedly positive responses to this test. *This test is not specific for lameness of the metacarpophalangeal joint.* I have seen marked responses in horses with navicular disease or osteoarthritis of the interphalangeal joints. However, horses with osteoarthritis, fractures of the metacarpophalangeal joint, or tenosynovitis usually also show

Fig. 8-1 • The lower limb flexion test is often erroneously called the *fetlock flexion test*. During the lower limb flexion test the fetlock, proximal interphalangeal, and distal interphalangeal joints are flexed; the palmar pastern and fetlock region soft tissue structures are compressed; and the dorsal structures are stretched.

a marked positive response. In a recent study of clinically sound horses in which lameness could consistently be induced by flexion with 250 N for 1 minute, lameness was alleviated by intraarticular analgesia of the metacarpophalangeal joint, but not by intraarticular analgesia of the proximal interphalangeal or distal interphalangeal joints or intrathecal analgesia of the navicular bursa.⁹ Exacerbation of lameness associated with pain arising from the SL after lower limb flexion is probably caused by relaxation of the SL during flexion and then sudden loading of the ligament when the horse starts to load the limb.

The limb should be held as close to the ground as possible, and forced carpal flexion should be avoided (see Figure 8-1). All soft tissue and bony structures in the palmar aspect of the distal limb are severely compressed, resulting in low specificity for the metacarpophalangeal joint. Some people use a hand as a fulcrum or grab the toe with both hands (Figure 8-2), but this technique may result in application of excessive force, although it otherwise produces similar results.

Fetlock Flexion Test

The specificity of the lower limb flexion test can be improved by applying force to the metacarpophalangeal joint and avoiding forced flexion of the interphalangeal joints. The fetlock flexion test is performed by placing one hand along the dorsal aspect of the pastern region and one hand along the dorsal aspect of the metacarpal region, while avoiding flexion of the carpus (Figure 8-3). When compared with lower limb flexion this test is more difficult to perform because it requires more force and the clinician's effort to maintain a similar degree of flexion. The test is not specific

Fig. 8-2 • Extreme lower limb flexion can be achieved by using both hands on the toe with the limb cradled between the clinician's legs. With such extreme flexion even normal horses may manifest a positive response.

Fig. 8-3 • A true fetlock flexion test can be performed by carefully flexing only the fetlock joint. The clinician's hand grasps only the pastern and not the toe of the hoof while avoiding forced flexion of the proximal and distal interphalangeal joints (see [Figure 8-1](#)).

for articular lameness of the metacarpophalangeal joint, and horses with soft tissue problems respond positively.

Flexion of Interphalangeal Joints

In my opinion, flexion of either the proximal interphalangeal or distal interphalangeal joint without concomitant flexion of the other, or of the metacarpophalangeal joint, is impossible. Varus or valgus stress can be applied to the interphalangeal joints, and when followed by trotting, this stress can be a suitable provocative test in horses with osteoarthritis or soft tissue injuries of these joints.

Carpal Flexion Test

The carpal flexion test is the most specific of all forelimb flexion tests, and a positive response usually reflects baseline lameness associated with the carpal region. Few false-positive results occur. A positive response may reflect intraarticular pain, but a positive response also is seen in horses with carpal tenosynovitis, accessory carpal bone fractures, proximally located superficial digital flexor (SDF) and deep digital flexor (DDF) tendonitis, PSD, or avulsion fracture of the third metacarpal bone (McIII) at the SL origin. Rarely, a horse with a problem in the scapulo-humeral and cubital joints or the antebrachium responds positively. A negative response does not preclude an articular lesion of the carpus, including incomplete fractures or sclerosis of the carpal bones.

The limb is elevated, and the carpus is forced into full flexion by pushing the metacarpal region directly underneath the radius ([Figure 8-4](#)). The distal limb can be pulled laterally to place the carpal joints in valgus stress or torsion.

Horses sometimes trot off lame on the contralateral limb after the carpal flexion test is performed. I have seen this most commonly in young Standardbred or TB racehorses with subchondral bone pain in the middle carpal joint and call it the "Ross crossed-extensor phenomenon." I believe that this reflects bilateral lameness, and flexion of the ipsilateral carpus causes less pain than making the horse stand for 1 minute on the contralateral limb. I have observed this response most commonly in horses with bilateral carpal lameness, but exacerbation of contralateral

Fig. 8-4 • The carpal flexion test is the most specific of all flexion tests, but it applies concomitant mild flexion of the elbow and shoulder joints. Although false-negative results are possible, a positive carpal flexion test result usually means that lameness originates from the carpal region.

Fig. 8-5 • Upper forelimb flexion is performed by grasping the antebrachium and pulling the entire limb caudally and slightly proximally. This maneuver flexes the shoulder joint and extends the elbow joint. Horses with shoulder region lameness often respond positively to this manipulative test.

lameness is not restricted to carpal lesions. Dyson¹⁰ has called this a "paradoxical response to flexion" and has observed exacerbation of contralateral lameness in horses with navicular syndrome, DDF tendon lesions in the digit, and distal hock joint pain.

Upper Limb Manipulation

Because of the inverse but simultaneous movement of the elbow and shoulder joints, it is difficult to accurately name the flexion tests of these joints. For instance, when the limb is pulled in a caudal direction, the shoulder joint is flexed but the elbow joint is extended. I call this manipulation *upper limb flexion* ([Figure 8-5](#)). This maneuver requires both

Fig. 8-6 • The upper limb extension test is performed by pulling the forelimb out in front of the horse and forcing it proximally. This places the elbow joint in flexion and the shoulder joint in extension. In my experience, lameness of the elbow region is exacerbated by this technique, but occasionally shoulder joint lameness also is worsened.

hands, one hand grasping the pastern region and one grasping the cranial aspect of the antebrachium to force the entire limb in a caudal direction. When the limb is pulled in a cranial direction, resulting in *upper limb extension*, the shoulder joint is extended, but the elbow joint is flexed (Figure 8-6). Both hands are placed around the pastern region while forcing the entire forelimb into maximal extension. Maintenance of upper limb extension or flexion for even 45 seconds is difficult, so I try to maintain this position for as long as possible and then evaluate the horse while trotting. Many normal horses resist upper limb manipulation, and an alternative is to force the limb into hard flexion or extension in a rhythmical fashion six to eight times and then trot the horse. Even though the entire limb is being manipulated, there are few false-positive test results. A horse with a positive response to carpal flexion may have a similar response to upper limb manipulation because it is difficult to perform upper limb flexion without simultaneously flexing the carpus. False-negative test results can occur, probably because of the inability to place either the shoulder or the elbow joints in hard flexion. In my experience, horses with lameness originating from the elbow region are more likely to respond to upper limb extension, whereas those with lameness originating from the shoulder region are more likely to respond to upper limb flexion.

Hindlimb Flexion Tests

Hindlimb flexion tests are not specific, but they may be useful to exacerbate the baseline lameness or detect hidden sources of potential lameness. I do not believe that hindlimb flexion tests are useful in differentiating the source of pain causing lameness in most horses unless the response is dramatic, and diagnostic analgesia usually is required in all horses.

Fig. 8-7 • The lower limb flexion test in the hindlimb is performed with the limb as close to the ground as possible. Flexion of one portion of the hindlimb is impossible without flexing the entire limb, a finding that explains many false-positive hindlimb flexion test results.

Lower Limb Flexion Test

The lower limb flexion test is performed similarly to the forelimb flexion test, but with similar force the metatarsophalangeal joint can be flexed more extremely. The veterinarian should try to keep the limb as low as possible to avoid placing hard flexion on the upper limb, although all joints are flexed to a degree. The lower limb flexion test also affects the proximal interphalangeal and distal interphalangeal joints and the surrounding soft tissues (Figure 8-7). Horses with digital flexor tenosynovitis or DDF tendonitis show a marked response to the lower limb flexion test. False-positive results can occur, but these are less common in a hindlimb than in a forelimb, even in horses in active work. Horses with pain in the upper limb may show a mild or moderate response to lower limb flexion. This test is not specific for pain located in the lower limb, and lameness in horses with stifle pain often is worse after the lower limb flexion test.¹⁰ Horses with subchondral bone pain from maladaptive or nonadaptive bone remodeling of the distal aspect of the third metatarsal bone (MtIII) or those with incomplete fractures of the MtIII or incomplete midsagittal fractures of the proximal phalanx may show little response to this test (false-negative result). Coupled with lack of effusion of the metatarsophalangeal joint, a false-negative response to lower limb flexion may sidetrack the clinician into thinking pain originates elsewhere. Diagnostic analgesia is required to determine the source of pain.

Fetlock Flexion and Interphalangeal Joint Tests

The metatarsophalangeal joint region can be flexed independently of the interphalangeal joints in the hindlimb, or the interphalangeal joints can be flexed independently, but these tests are difficult to perform and of limited value.

Upper Limb Flexion Test

The so-called “spavin test” or “hock flexion test,” misnomers for the upper limb flexion test, is *not specific for*

Fig. 8-8 • The hindlimb upper limb flexion test is demonstrated. This test has been called the *spavin test* or *hock flexion test*, but it is not specific for lameness of the hock. The hock and stifle joints are in forced flexion, the lower limb joints are flexed, the metatarsal region is compressed, and a small amount of forced flexion of the coxofemoral joint is induced.

lameness of the hock because the stifle and coxofemoral joints also are stressed hard, and mild flexion of the lower joints is inevitable. The terms *spavin test* and *hock flexion test* are deep-rooted in our profession but it is important to recognize that a positive response is *not* synonymous with distal hock joint pain.

The limb is held in hard flexion for at least 1 minute, but additional time for this test may improve its clinical value (Figure 8-8). It may be necessary to have an assistant place a hand on the contralateral hip to steady the horse, because proper performance of this test requires that the limb be elevated substantially, and the horse may lose its balance. The position of the hands in the metatarsal region is important to consider, because the force required to hold the hindlimb in this position may cause compression and pain in structures along the plantar aspect, potentially contributing to a false-positive response.

Hindlimb Flexion Test

Alternatively, the entire hindlimb can be flexed simultaneously. This test is useless in differentiating potential sources of pain in a limb, but it is quite useful in exacerbating baseline lameness or uncovering occult lameness conditions. The clinician's hands are placed on the toe and the entire limb is held in extreme flexion (Figure 8-9). An assistant may be necessary to steady the opposite hip while the limb is elevated.

"Hock" Extension Test

Hock extension may be useful in placing selective stress on the hock, independent of the stifle. Forced extension causes tension on the soft tissue structures on the dorsal, medial,

Fig. 8-9 • A hindlimb flexion test is a combination of the lower limb flexion and upper limb flexion tests.

Fig. 8-10 • During the hock extension test the clinician forces the hock into extension by pushing down on the calcaneus while pulling up on the distal limb by using both the right arm and left leg. Pain from hock lameness can be exacerbated, but false-positive results from pain in other locations also can occur.

and lateral aspects of the hock. Seldom is it possible to perform this test for 1 minute; six to eight attempts at forced extension followed by trotting the horse can be substituted for more lengthy manipulation (Figure 8-10). False-positive and false-negative responses occur, which are caused mostly by the inelastic reciprocal apparatus. This

Fig. 8-11 • A seldom-used test is the stifle flexion test. This test can be difficult and dangerous to perform in fractious horses. The forced flexion of the stifle joint used in this test attempts to differentiate stifle and hock joint pain.

maneuver can reveal laxity of a damaged fibularis (peroneus) tertius.

“Stifle Flexion” Test

A modification of the upper limb flexion test can be used to place hard flexion on the stifle, independent of the hock (Figure 8-11). This test can be somewhat difficult to perform but may exacerbate lameness in horses with osteoarthritis or other conditions of the stifle. Other proximal limb joints are also in flexion; therefore some false-positive results occur. See page 87 for other manipulation of the stifle.

DIRECT OR LOCAL PALPATION FOLLOWED BY MOVEMENT

Static palpation, in which the horse’s response to compression during palpation while standing is assessed, reveals useful information (see Chapter 6). Additional information can be gained by evaluating movement after palpation and dynamic provocation to induce lameness. Dynamic provocation usually is performed by digital palpation or use of hoof testers. Many horses manifest a positive response during static palpation, but the primary pain is located elsewhere. However, if lameness can be induced or baseline lameness can be increased by one or two grades by deep palpation, then the area may be relevant to the current cause of lameness. False-positive results do occur, but in my opinion these are less frequent than with most flexion tests. There are few false-negative results.

Digital Compression of a Painful Area

The veterinarian should elevate the limb and compress the painful or otherwise inflamed area for 15 to 30 seconds and then evaluate the horse at a trot in hand. Exacerbation of the baseline lameness by one or more grades is considered

a positive response. This procedure is useful in differentiating the cause of lameness in both the forelimb and hindlimb. In the forelimb, I find it useful to compress the dorsal proximal aspect of the proximal phalanx (if a midsagittal fracture is suspected), the dorsal cortex of the McIII (for bucked shins or a dorsal cortical fracture), exostoses involving the small metacarpal bones (for splints), the suspensory branches or digital flexor tendons, and the proximal palmar metacarpal region (for PSD or longitudinal or avulsion fracture of the McIII). In horses with mild SDF tendonitis, baseline lameness usually is mild or nonexistent, but obvious lameness after digital compression suggests tendonitis as a clinically significant problem.

In the hindlimbs, compression of the dorsal proximal aspect of the proximal phalanx can increase lameness from midsagittal or dorsal frontal fracture, but trauma from interference injury (of particular importance in trotters) or other forms can lead to a false-positive response. A *dynamic Churchill test*, compression followed by trotting (see Chapter 6), is useful in the diagnosis of lameness of the proximal metatarsal region and tarsus. In the hindlimb, compression of the proximal aspects of both the second and fourth metatarsal bones puts indirect pressure on the origin of the SL, and a positive response may indicate PSD. False-positive results to this provocative test are common because the entire hindlimb is in flexion, similar to upper limb flexion without compression. Compression of a “curb” followed by trotting may increase lameness.

In some horses with tibial stress fractures, an induced lameness can be seen after deep palpation of the caudal tibial cortex. With the limb elevated, the veterinarian should apply deep pressure to the caudal cortex by wrapping the fingers around the tibia from the medial aspect (see Figure 6-27). Most horses object to this maneuver, but in those with tibial stress fractures, the positive static response is followed by an exacerbation of the baseline lameness.

Axial Skeleton

Application of direct local pressure to many parts of the axial skeleton is difficult, but in some instances this procedure can lead to the detection of pain both statically and while the horse is trotting (see Chapters 6, 93, 95, and 97). In the cervical area, forced lateral bending followed by walking or trotting may exacerbate neurological signs or gait deficits in horses with cervical instability or proliferative changes. Deep palpation over the thoracolumbar spine followed by trotting can induce hindlimb stiffness or other mild gait abnormalities. Direct and deep palpation over the tubera sacrale and tubera coxae can induce hindlimb lameness in horses with stress fractures or those with chronic lameness as a result of pelvic asymmetry from old fractures. Sacroiliac compression, or manipulation of the sacrum or tail head, can induce hindlimb stiffness or lameness in horses with injuries in these areas.

INDUCED LAMENESS AFTER HOOF TESTER EXAMINATION

The hoof testers are applied in a suspected area for 15 to 30 seconds and the horse is evaluated for lameness while trotting. False-positive test results are quite common, but

a marked difference between limbs can be an important clinical sign. Shoes and pad combinations may preclude complete hoof tester examination of the sole, so I often apply pressure across the heel. I have found this position to yield the most useful information in horses with palmar foot pain from most causes, but it also induces a positive response in horses with nonspecific foot pain (sore feet). Most normal horses object to firm pressure placed across the heel using hoof testers, particularly in a hindlimb, and mild lameness on the initial few steps is common, but severe lameness after this test is a useful indication that the foot is the source of baseline lameness.

THE WEDGE TEST

The *wedge test* is a form of manipulation similar to the flexion or other varus or valgus stress tests, but it is used specifically to evaluate the digit and associated soft tissues. The wedge can be used to dramatically change the dorsal-to-palmar (heel) or medial-to-lateral hoof angles. Collateral ligaments, joint capsules, subchondral bone and articular surfaces, and surrounding soft tissues can be stretched or compressed when the horse stands on the wedge. Changes in hoof angles of this magnitude can greatly change the stress placed on the DDF tendon, SDF tendon, and SL. Raising the heel reduces stress on the DDF tendon but increases stress on the SL. Raising the toe reduces stress on the SL but increases stress on the DDF tendon, navicular bone, and associated ligaments and bursa. The number of tissues affected by the wedge accounts for the lack of specificity of this test, and it likely accounts for many false-positive results. The wedge is placed in the desired position, and the horse is made to stand in this position for 30 to 60 seconds with the contralateral limb elevated (Figure 8-12). The horse is then trotted in a straight line on a firm surface. The test can be used in any limb but is performed most commonly in the forelimbs. In some horses, it is difficult to attain the desired duration regardless of whether they are lame. The horse's response to simply standing on the wedge may not give an accurate indication of how lame it will be when it is trotted. In horses content to stand in such an abnormal position, a dramatic lameness may be seen at the trot. Horses with navicular syndrome or sore feet from many causes of palmar foot pain are most likely to manifest a positive response. In my experience and that of others, the direction of the wedge that elicits the most positive response from horses with palmar foot pain is with the apex (low end) directed medially (see Figure 8-12).¹¹ This substantial change in the medial-to-lateral hoof angle is likely to cause stretching of the suspensory apparatus of the navicular bone and collateral ligaments of the distal interphalangeal joint or compression on articular structures. Horses with palmar foot pain may show severe lameness, but diagnostic analgesia is required to confirm the foot as a source of pain. Horses with injuries of the DDF tendon, SDF tendon, and SL may show a milder response.

VARUS OR VALGUS STRESS TESTS

Evaluation for lameness after placing varus or valgus stress on an individual joint may incriminate this area as a potential source of pain and is used most commonly in the stifle.

Fig. 8-12 • A 15- to 20-degree wedge can be used to manipulate the joints and soft tissue structures of the digit. The most consistent response is elicited by directing the apex (low end) of the wedge medially (as shown). The wedge also can be used to raise the heel and toe. (Wedge courtesy Norman G. Ducharme, Ithaca, New York.)

To perform the stifle valgus stress test, the clinician's shoulder (or hand) is used as a fulcrum against the distal femur, and the distal limb is pulled laterally several times before the horse is trotted (see Figure 6-25). False-positive results can be obtained because the entire distal extremity is manipulated during this test. Valgus or varus stress tests can be used in many joints in the distal limb, particularly the interphalangeal joints.

Patellar manipulation followed by trotting (see Figure 6-26) may be helpful but can be difficult to perform when horses resist forced proximal movement of the patella (frequently, the veterinarian's wrist is forced into hyperextension). Although cranial and caudal draw tests can be used to exacerbate stifle lameness, I have not found them particularly helpful, and they are dangerous to perform.

FLEXION TESTS AND DIAGNOSTIC ANALGESIA

I do not generally recommend combining the results of flexion tests and diagnostic analgesia (called "blocking the flexion test"). I often hear that baseline lameness abated after a block, but the horse still had positive flexion test results. My usual comment is, "Why bother to flex the horse if baseline lameness has been abolished?" Flexion tests induce lameness that may be unrelated to the baseline lameness, a concept that is confusing to the inexperienced and to lay people. Thus it is not unusual that a horse might have residual lameness after flexion, even if the baseline lameness has been eliminated.⁴ I usually do not recommend further investigation once baseline lameness has been eliminated.

If baseline lameness is not obvious but a low-grade gait deficit is present, or if a horse has bilaterally symmetrical lameness, flexion tests or other forms of manipulation or provocation may be the only way of “seeing” lameness. In this instance, induced lameness from manipulation can be

assumed to be the baseline lameness, and diagnostic analgesia can proceed. All involved parties should be well informed about the potential for misdiagnosis, but in certain circumstances this pathway may lead to a successful diagnosis.

Chapter 9

Applied Anatomy of the Musculoskeletal System

Matthew Durham and Sue J. Dyson

It is beyond the scope of this book to describe all aspects of musculoskeletal anatomy in depth, yet a detailed knowledge of anatomy is fundamental to a lameness diagnostician, as highlighted in the chapters on observation and palpation (see Chapters 5 and 6). Some aspects of anatomy are considered in depth in individual chapters dealing with conditions of specific areas. This chapter considers some philosophical aspects of the importance of anatomical knowledge and describes some basic principles. It also provides illustrations that we hope will help the reader to understand better the three-dimensional aspects of anatomy.

Accurate interpretation of what we see and feel during an examination requires knowledge of what structures we are looking at and palpating. For example, a swelling is noted over the dorsal aspect of the carpus. Is the swelling diffuse and possibly related to a hygroma, periarticular edema, or cellulitis, or is there a discrete swelling, horizontally oriented, reflecting distention of the middle carpal joint? Or is it a longitudinal swelling reflecting distention of the common digital extensor tendon sheath or the tendon sheath of the extensor carpi radialis? If the swelling is longitudinal, are any compressions in the swelling caused by normal retinaculum or adhesions within the sheath (Figure 9-1)? If we examine the sheath by ultrasonography, is the echogenic band extending from the sheath wall to the enclosed tendon normal mesotendon, or is it an adhesion? If diffuse swelling is present around the dorsal aspect of the carpus associated with lameness, how can we tell if the middle carpal joint capsule is distended? We need to know that there is a palmar outpouching of the middle carpal joint on the palmarolateral aspect of the carpus, just distal to the accessory carpal bone. Thus during visual inspection and palpation the clinician should be constantly asking, “What structure am I seeing or palpating, what are its functions, and what would be the consequences of loss of function?” If it has abnormal contour or size, is this the result of swelling of that structure or of an adjacent or underlying structure? Having established what structure is abnormal, the clinician then must consider the best imaging modality. If it is a tendonous or ligamentous

structure, ultrasonography probably will provide the most information, but we must remember that it has bony attachments, and damage at those attachments might best be assessed by either radiology or nuclear scintigraphy. So we need to know not only what each structure is, but also the structures to which it is attached.

During visual inspection and palpation, we also need to think logically. We know that the superficial and deep digital flexor tendons (SDFT, DDFT), the accessory ligament of the DDFT (ALDDFT), and the suspensory ligament (SL) lie on the palmar aspect of the third metacarpal bone (McIII) (Figure 9-2). Swelling confined to just the medial aspect of the metacarpal region is far more likely to reflect direct trauma to the medial aspect of the limb than sprain or strain of any of the ligamentous or tendonous structures. We need to know that the proximal aspect of the SL lies between the bases (heads) of the second and fourth metacarpal bones and therefore is inaccessible to direct palpation, and that desmitis often may be present without discernible soft tissue swelling (Figure 9-3).

Fig. 9-1 • Sagittal anatomical section through the carpus, transecting the extensor carpi radialis tendon (ECRT). C3, Third carpal bone; ICB, intermediate carpal bone.

Fig. 9-2 • Sagittal views of the palmar metacarpal region. Proximal is to the right. **A**, FreeStyle Extended Imaging (Sequoia model, Acuson, Mountain View, California, United States) ultrasonographic image of the palmar metacarpal region. **B**, Corresponding anatomical section. *DDFT*, Deep digital flexor tendon; *ICL*, accessory ligament of the DDFT (inferior check ligament); *SDFT*, superficial digital flexor tendon; *SL*, suspensory ligament.

We must be aware of anatomy to realize the possible consequences of trauma to an area. The paucity of soft tissues over the cranial aspect of the stifle makes the patella and the tibial tuberosity vulnerable to direct trauma, hence the risk of fracture after hitting a fixed fence. The lack of soft tissues also means that if the horse hits a thorn hedge, the possibility of a thorn penetrating the femoropatellar joint capsule, resulting in contamination and infection, is quite high. We also need to think about how structures move relative to one another while the horse is in motion. If a steeplechase horse sustains an interference injury on the palmar aspect of the metacarpal region while galloping, the position of the skin laceration probably will not coincide with the level of the laceration in the SDFT (Figure 9-4). We also need to know the relative positions of the laceration and the digital flexor tendon sheath to be aware of the likelihood that the sheath may have been traumatized, and thus the risk of infectious tenosynovitis. Faced with a contaminated wound on the dorsal aspect of a hind fetlock and severe lameness, and the possibility of infection of the metatarsophalangeal joint, we need to know where to expect to see distention of the plantar pouch of the joint capsule and to know that this site is safely accessible for arthrocentesis.

A fundamental principle of lameness investigation is the identification of the source or sources of pain. Although this may be possible through detailed clinical examination, in many instances it is essential to perform diagnostic analgesia (see Chapter 10). A detailed knowledge of the anatomy of nerves, joint capsules and the various out-pouchings, tendon sheaths, and bursae is fundamental to

Fig. 9-3 • Transverse sections through the proximal metacarpal region. Dorsal is to the top and lateral is to the left. **A**, Anatomical specimen. **B**, Computed tomographic scan using soft tissue windowing. *DDFT*, Deep digital flexor tendon; *ICL*, accessory ligament of the deep digital flexor tendon (inferior check ligament); *SDFT*, superficial digital flexor tendon; *SL*, suspensory ligament.

safe, accurate performance of perineural and intrasynovial injections.

Given the knowledge of the close relationship among the distal interphalangeal joint capsule, the distal sesamoidian impar ligament, the collateral sesamoidian ligaments and the distal phalanx, and the close proximity of branches of the palmar digital nerve, it is not surprising that intra-articular analgesia is not specific and that other structures

Fig. 9-4 • Lateral scintigraphic image of the metacarpal region acquired before the end of the flow (vascular) phase and at the beginning of the pool phase. This jumper had a history of low-grade chronic desmitis of the proximal aspect of the suspensory ligament (*SL*), and mild diffuse superficial digital flexor (*SDFT*) tendonitis. An acute interference injury to the midmetacarpal region was evident on the skin. Note the proximal location of the acute injury to the SDFT. The linear area of uptake between the *SL* and *SDFT* is vascular artifact related to the time of acquisition.

can be affected, especially if interpretation of the response is delayed or an excessively large volume of local anesthetic solution is used. Knowledge that the medial and lateral femorotibial joints do not normally communicate and that the cruciate ligaments usually are extraarticular structures is crucial for an understanding of why these joint compartments must be injected separately, and why the response to intraarticular analgesia may be both incomplete and delayed if a cruciate ligament is damaged.

Knowledge of functional neuroanatomy also is important for interpretation of specific gait abnormalities. Inability to bear weight on a hindlimb after general anesthesia may be the result of myopathy, but in the absence of marked pain and distress, it is more likely that the horse has lost extensor function and is unable to extend any of the hindlimb joints because of femoral nerve paresis. Loss of ability to extend the elbow may result from loss of triceps function associated with a fracture of the olecranon but may also be caused by radial nerve paresis.

Vascular anatomy is important because many nerves lie close to vessels. With superficial nerves and vessels, identification of the vessel may facilitate palpation of the nerve and thus aid accurate perineural injection. Avoiding penetration of the vessel and causing hematoma formation also is desirable. With regard to deeper nerves the veterinarian may benefit by knowing that the needle must be in close proximity to the nerve if blood appears in the needle hub. This information can be helpful when performing perineural analgesia of the deep branch of the fibular nerve.

Assessment of digital pulse amplitudes is an integral part of palpation. Increased pulse amplitude usually signifies a site of inflammation at, or distal to, the region of

Fig. 9-5 • Sagittal anatomical section through the pastern demonstrating a common location for the nutrient foramen (*NF*) entering the proximal phalanx (*P1*). *MC3*, Third metacarpal bone; *P2*, middle phalanx.

palpation, especially in association with inflammatory conditions of the foot, such as subsolar abscessation or laminitis. Palpation of the pulse in the dorsal metatarsal artery and assessment of saphenous vein filling can be helpful in the evaluation of a horse with suspected aortoiliac thrombosis.

Knowledge of the sites of major vessels is important when considering the consequences of major laceration to an area and possible avascular areas, and in planning a surgical approach to an area. All bones have one or more nutrient foramina through which major vessels enter. These usually are in standard locations (*Figure 9-5*). Knowledge of these sites is critical for accurate radiological interpretation because a nutrient foramen appears as a radiolucent area, which should not be confused with a pathological lesion. The position of these intraosseous vessels also has important consequences in considering repair of major long bone fractures.

Thermography relies on the detection of surface heat and is obviously greatly influenced by the position of superficial vessels. Interpretation may be misleading without knowledge of location. Thus it should be absolutely clear that anatomy is a dynamic subject and is not merely a function of knowing the origins and insertions of numerous structures.

We also need to know some fundamentals of biomechanics. What is the biomechanical function of the *SL*? What are the implications of loss of function? For example, how may function be altered by a change in foot angle after application of a heel wedge? How is load in the distal limb

Fig. 9-6 • The oblique distal sesamoidean ligaments. **A**, Frontal magnetic resonance image (MRI) of the pastern showing the origins and insertions of the oblique distal sesamoidean ligaments (ODSL). **B**, Frontal (left) and transverse (right) ultrasonographic images of the ODSLs obtained at point **B** in **A**. joints affected by mediolateral foot imbalance? If the accessory ligament of the SDFT is cut (superior check desmotomy), how does this alter the function of not only the SDFT but also other tendonous and ligamentous structures? Does consequent overload of the SL predispose to an increased risk of suspensory desmitis? When orthopedic surgery is being considered, which is the tension side of the bone, to which a bone plate should be applied to take advantage of the tension band principle?

In more general terms, how will lameness in the left hindlimb alter forces in the other limbs, and does this vary with the gait? Given the reciprocal apparatus of the hindlimb and the inability to flex and extend the limb joints independently, it is not surprising that the gait characteristics of hindlimb lameness are so similar, irrespective of the source of pain causing lameness. Understanding the reciprocal apparatus in addition to the results of loss of its function (e.g., after damage to the fibularis tertius) is hugely important for an understanding of hindlimb lameness.

After the source of pain causing lameness has been isolated, then it is necessary to establish what is causing pain; this requires one of a number of imaging modalities: radiography, ultrasonography, nuclear scintigraphy, magnetic resonance imaging (MRI), computed tomography (CT), and exploratory arthroscopy, bursoscopy, or tenoscopy. Accurate interpretation of the findings from any of these techniques requires specialist anatomical knowledge.

With radiographic images, various structures are superimposed, resulting in potentially confusing radiolucent lines that can mimic a fracture (e.g., in the relatively complex carpus and tarsus). A frog shadow superimposed over the navicular bone may mimic a fracture. We must be cognizant of anatomical variations, for example, the shape and size of the crena of the distal phalanx. We have to know how best to image a specific anatomical location, such as the sustentaculum tali of the calcaneus (fibular tarsal bone) using a skyline projection. For interpretation of the clinical significance of periosteal or entheses new bone, detailed knowledge of the soft tissue structures that do (or do not) attach in that area is vital. Particularly in the fetlock and pastern areas, numerous ligamentous structures have discrete areas of attachment (Figure 9-6).

Radiography requires the awareness that we are looking at a three-dimensional structure in two dimensions, and thus images of the area must be obtained from several different angles. With ultrasonography, and more particularly with MRI and CT, structures can be imaged in three dimensions; this requires detailed knowledge of the shape, size, and relationships among structures. In the proximal metatarsal region the DDFT lies more medial than the SDFT and SL, and thus these structures cannot be imaged adequately by ultrasonography at the same time from the plantar aspect of the limb (Figure 9-7). The transducer must be moved to a plantaromedial site to evaluate the DDFT in its

Fig. 9-7 • Transverse anatomical section of the proximal metatarsal region demonstrating the lateral position of the superficial digital flexor tendon (SDFT) relative to the deep digital flexor tendon (DDFT). Lateral is to the left and dorsal to the top of the image. This arrangement is the opposite of that seen in the forelimb (compare with Figure 9-3). MT2, MT3, and MT4, Second, third, and fourth metatarsal bones, respectively; SL, suspensory ligament.

entirety. A large vessel on the plantarolateral aspect of the SL can cause shadowing artifacts in the SL.

The internal architecture of the joint becomes important during exploratory arthroscopy. What are the normal variations in cartilage thickness? Where do you expect to see a synovial fossa? Which parts of the synovial membrane are usually more vascular? Is it normal that the cranial cruciate ligament can be seen without synovial covering from the medial femoral tibial joint?

A textbook of this type cannot possibly provide detailed descriptions of all aspects of anatomy, functional anatomy, and biomechanics, nor answer all of the questions posed earlier in this chapter. It is hoped that this overview will stimulate readers to have a thirst for more knowledge of these subjects, in the understanding of their huge importance.

Lameness clinicians are encouraged to acquire a set of boiled-out bones for reference and perform detailed dissections of cadaver limbs to improve knowledge of anatomy. Practicing nerve block techniques on cadaver limbs is very important for inexperienced clinicians or those performing a new block for the first time. If a lame horse must be humanely destroyed, clinicians should take the opportunity, whenever possible, to perform a postmortem examination to correlate clinical findings with the actual lesions and revise anatomy at the same time. Each time a dissection is performed, new anatomical detail becomes apparent that previously may have been missed.

The remainder of this chapter provides some basic definitions of anatomical terms used elsewhere in the book, describes the reciprocal apparatus of the forelimb and

hindlimb, and presents correlative illustrations of anatomical specimens and images of those areas to assist in the understanding of three-dimensional anatomy.

THE LANGUAGE OF ANATOMY

The system described in the *Nomina Anatomica Veterinaria* (NAV) according to the guidelines of the International Committee on Veterinary Anatomical Nomenclature has been used so that anatomical terminology is universal. English translations of NAV terms have been used whenever possible according to these guidelines.

FORCES

The interaction of anatomical structures allows for the conversion of chemical energy into purposeful movement. It is often useful to think of complex anatomical structures in terms of interactions between simplified structural units. The interaction of forces within these anatomical units dictates the abilities and the potential weaknesses of the equine athlete. In simple terms, the stresses acting on the body are compression, tension, shear, torsion, and bending.

Compression is the force applied between two points to move them together. Examples of compression are seen in joints, such as within the middle carpal joint at the interface between the radial and third carpal bones, or the compression sustained by the digital cushion between the sole, frog, and the distal phalanx. Compression also is sustained within most bones, such as the third carpal bone or the dorsal cortex of the McIII.

Tension is the force that tends to stretch or elongate a structure. Examples of tension are most obvious in tendons and ligaments, but bones such as the olecranon or within the palmar cortex of the McIII also sustain tensile strain.

Shear is a stress at the interface between two structures moving in opposite directions. Examples of shear are seen in the femoropatellar and tarsocrural joints, within bone, and within the hoof capsule.

Torsion is the stress produced when a twisting motion is applied to an object. Examples of torsional stress are seen within joints, such as the distal hock joints, or within individual bones, such as the McIII.

Bending is a combination of compression on one side of a structure and tension on the other side. Structures subjected to bending are long bones such as the McIII, where the dorsal cortex is subjected to compression, whereas the palmar cortex is subjected to tension.

SPECIALIZED STRUCTURES

Synovial Structures

Synovial bursae, tendon sheaths, and joints have a similar function and generally similar structure. All are sacs containing synovial fluid produced by the lining of the sac. In simple terms, synovial structures facilitate the movement between independent structures by providing a hydraulic cushion of viscous fluid that limits the effects of friction to help dissipate compressive and shear forces. (For a more complete discussion on synovial structures, see Chapters 61 to 67 and 74 to 79.)

Fig. 9-8 • Transverse anatomical section through distal aspect of the tibia and proximal aspect of the calcaneus demonstrating the distinct calcaneal bursa bounded by the collateral ligaments of the superficial digital flexor tendon (SDFT). DDF, Deep digital flexor muscle.

A diarthrosis is a mobile joint containing a synovial membrane. This membrane is flexible enough to allow for movement of the joint. The synovial fluid lubricates, hydraulically equalizes pressure between cartilage plates, and nourishes the articular cartilage.

A synovial sheath is a sac that completely surrounds a tendon, forming a synovial lining on the surface of the tendon and the lining of the sheath. The synovial reflection between these visceral and parietal layers is termed the *mesotendon*. This structure is similar to the mesentery in the abdominal cavity. Nerve and blood supply to the tendon is found within the mesotendon. In areas of great mobility within the synovial sheaths, the nerve and blood supply to the tendons is through a vinculum, which is a modified mesotendon in the form of a narrow band connecting visceral and parietal layers.

A synovial bursa is a simple sac lying between a tendon or muscle and an adjacent bony prominence. A bursa does not surround the tendon but acts as a cushion at the interface where pressure is concentrated (Figure 9-8).

Intercalated Bones

Intercalated bones are bones that arise within tendons or ligaments allowing for the interface between the tendinous structure and the underlying bone at an area of focal pressure, typically at the level of a joint. The interface between these bones is within a synovial sac. The navicular bone, proximal sesamoid bones (PSBs), and patella are intercalated bones. These bones allow for smooth movement and dissipation of focal pressure between the tendon or ligament and the underlying joint (Figure 9-9).

Fig. 9-9 • **A**, Oblique radiographic image of a normal proximal sesamoid bone (PSB). **B**, Parasagittal anatomical section through suspensory branch, PSB, and oblique distal sesamoidean ligament (ODSL).

Fibrocartilaginous Structures

In general terms, there are four functional arrangements of fibrocartilage: interarticular, connecting, circumferential, and stratiform.

Interarticular Fibrocartilage

Menisci are fibrocartilaginous structures located between the articular cartilages of a diarthrosis. Menisci are not directly attached to the joint surfaces but are held in place by ligaments immediately adjacent to the articular surfaces. They provide congruency between the condyles, allow for a greater range of movement of the joint, and absorb concussion. Menisci are found in the stifle and temporomandibular joints of the horse.

Connecting Fibrocartilage

A symphysis is a fibrocartilaginous joint that allows minimal movement. The pelvic symphysis and intervertebral and intervertebral joints are examples of fibrocartilaginous joints.

Circumferential Fibrocartilage

In the coxofemoral joint the acetabular lip (labrum acetabulare) is a fibrocartilaginous ring extending the articular surface in a firm, semiflexible manner. The transverse acetabular ligament is the portion of the labrum crossing the acetabular notch. The glenoid labrum seen in other species is a poorly developed fibrous band in the shoulder of the horse.

Stratiform Fibrocartilage

Stratiform fibrocartilages arise within ligamentous structures at an interface with high focal pressure between soft tissue and bone, either within a ligament or as an extension of a bony surface. These structures are similar to intercalated bones in that they typically provide rigidity to help dissipate compressive forces, but the moderate elasticity allows for some flexibility of the structures.

The parapatellar fibrocartilage on the medial aspect of the patella, portions of the biceps brachii tendon of origin within the intertubercular (bicipital) bursa, the manica flexoria, and portions of the DDFT adjacent to the proximal aspect of the middle phalanx are examples of stratiform cartilage formation within tendonous structures. The proximal, middle, and distal scuta are stratiform fibrocartilaginous structures associated with the intersesamoid ligament, the palmar aspect of the middle phalanx, and the collateral sesamoidean ligaments, respectively. These structures serve as semirigid pulleys primarily for the DDFT.

PASSIVE STAY APPARATUS

Distal Limb

The horse is uniquely equipped to be able to stand at rest while expending minimal muscular effort. In the forelimb and hindlimb the fetlock is prevented from overextension by a combination of structures providing passive resistance. The suspensory apparatus is the main contributor, forming a sling that maintains the fetlock in extension. In addition, the SDFT, DDFT, and the associated accessory (check) ligaments (in the forelimb) act as tension bands providing passive support. The suspensory apparatus consists primarily of the SL and branches, PSBs, and distal sesamoidean ligaments. The intercalated PSBs provide a broad face at the point where focal pressure is high at the palmar or plantar aspect of the fetlock joint, enabling the ligamentous tension band to support the fetlock. Dorsal branches of the SL join with the common or long digital extensor tendon, helping to stabilize the dorsal aspect of the digit. The axial and abaxial palmar and plantar ligaments of the proximal interphalangeal joint, the SDFT branches, and the straight sesamoidean ligament support the palmar or plantar aspect of the proximal interphalangeal joint. The navicular bone and its suspensory apparatus, in combination with the distal sesamoidean impar ligament, stabilize the palmar or plantar aspect of the distal interphalangeal joint.

Fig. 9-10 • The passive stay apparatus of the forelimb.

Forelimb

In the forelimb the fibrous portion of the serratus ventralis thoracis acts as a sling suspending the thorax from the forelimb by its attachment to the scapula. The downward force applied by the serratus ventralis on the caudal aspect of the scapula causes slight flexion of the scapulohumeral joint, applying tension to the biceps brachii. A fibrous band of the biceps brachii extends from the supraglenoid tubercle of the scapula and continues as the lacertus fibrosus, which joins with the extensor carpi radialis to passively extend the carpus. Minimal muscular effort by the triceps on the olecranon maintains the elbow in extension (Figure 9-10).

Hindlimb

The stifle is maintained in extension by the patellar locking mechanism with minimal muscular effort. Slight muscular effort by the quadriceps and tensor fasciae latae rotates the patella medially, where the cartilaginous process of the

Fig. 9-11 • The patellar locking mechanism.

patella is caught caudal to the large prominence of the medial trochlear ridge of the femur. Slight relaxation of the quadriceps as a whole allows slight flexion of the stifle, which “locks” the patella in place by applying tension primarily to the medial and middle patellar ligaments (Figure 9-11). When the stifle is extended, the hock is passively extended by the superficial digital flexor and the fibrous component of the lateral head of the gastrocnemius muscles, which extend from the femur to the tuber calcis.

The reciprocal apparatus forces the hock to flex and extend in unison with the stifle. The reciprocal apparatus transfers mechanical energy to the distal aspect of the limb from the massive muscular structures of the upper limb without adding mass to the lower limb. The superficial digital flexor and the fibrous portion of the gastrocnemius muscles serve as the caudal component of the reciprocal apparatus, along with the long plantar ligament, which acts as a tension band to make the calcaneus, distal aspect of the tarsus, and metatarsal region a single functional lever arm. The fibularis (peroneus) tertius serves as the cranial component of the reciprocal apparatus, extending from the femur to the dorsal and lateral aspects of the tarsus (Figure 9-12). Although the fibularis tertius is important as part of the reciprocal apparatus, it is not essential for function of the passive stay apparatus, because its function is flexion of the tarsus.

Fig. 9-12 • The reciprocal apparatus. DDFT, Deep digital flexor tendon; SDFT, superficial digital flexor tendon.

A second reciprocal mechanism has been described for the lower hindlimb, where the fetlock and digit are flexed at the same time as the stifle and hock. The long digital extensor tendon and DDFT were the dorsal and plantar components suggested, but the SDFT probably also contributes.

THREE-DIMENSIONAL ANATOMY

Major advances in lameness diagnosis are being made with the assistance of advanced imaging techniques. Radiography, nuclear scintigraphy, and ultrasonography are well established, whereas CT and MRI are growing in importance. CT and MRI in particular require a detailed knowledge of three-dimensional anatomy. It is beyond the scope of this text to provide detailed correlative images of the entire musculoskeletal system. Figures 9-13 through 9-18 give a flavor of what is possible. Figures 9-13 through 9-16 highlight the complex anatomy of the navicular

bone region, showing the close relationship between the collateral sesamoidean ligaments, the distal sesamoidean impar ligament, the DDFT, and the navicular bursa and

distal interphalangeal joint capsule. Figures 9-17 and 9-18 demonstrate the relationship among some aspects of the complex anatomy of the carpal region.

Chapter 10

Diagnostic Analgesia

Lance H. Bassage II and Mike W. Ross

Despite the many technological advances in equine sports medicine over the past three decades, diagnostic analgesia arguably remains the most valuable tool in the equine clinician's arsenal to localize pain causing lameness. Although the technique requires a thorough understanding of anatomy, basic technical skill, and clinical experience, the equipment and expense are minimal. In addition, diagnostic analgesia can be performed on site, with the outcome immediately obvious. Any lingering concern that a suspected "shoulder problem" exists is convincingly erased when the response to perineural analgesia of the digit is observed. This chapter reviews the various perineural, intrasynovial, and local (regional) infiltration techniques for application of local analgesia in the diagnosis of lameness in horses.

LOCAL ANESTHETICS: PHARMACOLOGY AND TISSUE INTERACTIONS

Pain is transmitted specifically in the small, lightly myelinated, A delta and nonmyelinated C nerve fibers.¹ All commonly used local anesthetic solutions, regardless of the specific molecular structure, share the same basic mechanism of action—specifically, the ability to block or inhibit nociceptive nerve conduction by preventing the increase in membrane permeability to sodium ions.² These agents consist of a lipophilic and a hydrophilic group, connected by an intermediate chain containing a carbonyl group of an amide or ester linkage, and have traditionally been categorized as either amide- or ester-type local anesthetics.³ Common local anesthetic solutions used in horses—2% solutions of lidocaine, mepivacaine, and bupivacaine—are of the amide type.

Compared with most local anesthetics, lidocaine and mepivacaine are considered relatively fast-acting and have a reported duration of action of 1½ to 3 hours and 2 to 3 hours, respectively. In contrast, bupivacaine is intermediate in onset but has a much longer duration of action (3 to 6 hours).⁴ Bupivacaine is most suited for providing therapeutic rather than diagnostic analgesia. The results in

clinical practice vary, because in *severely* lame horses the degree and duration of local analgesia are decreased, regardless of the agent used.

When local anesthetic solutions are injected, tissue damage can occur but is extremely rare.^{3,4} Soft tissue swelling occurs occasionally and is likely caused by needle trauma or hematoma formation and not from a direct drug-tissue interaction. We suggest that alcohol and a clean wrap be applied to the injection sites when the diagnostic evaluation is complete to prevent or minimize swelling at injection sites. Cellulitis or other forms of infection are rare potential complications.

Acute synovitis, or *flare*, is a rare complication that can occur after intrasynovial (most commonly intraarticular) injection of local anesthetic solutions. Synovitis from intrasynovial injection of local anesthetic solution is much less common than from injection of other medications. Mepivacaine is thought to be less irritating than lidocaine when administered intraarticularly, but we have not recognized this difference.³ However, Dyson reported that lidocaine may be considerably more irritating than mepivacaine, and clinical data documenting differences were used successfully in the licensing of mepivacaine in the United Kingdom.⁵ Like cellulitis after perineural injections of local anesthetic solutions, infectious synovitis is a rare but possible sequela. To mitigate the possibility of contaminated solution, we use a new vial of local anesthetic solution when performing intrasynovial analgesic procedures.

Systemic side effects from diagnostic analgesic techniques are exceedingly rare. Cardiovascular or central nervous system signs, including muscle fasciculation, ataxia, and collapse, were reported.³ Systemic intoxication would require a dose much higher than is commonly used, even for an extensive diagnostic evaluation. For example, the maximum single infiltration dose of lidocaine that can be safely administered to a 500-kg horse is about 6.0 g, or 300 mL of a 2% solution.⁶

Strategy, Methodology, and Other Considerations

A few basic principles must be followed to ensure success. A thorough working knowledge of regional anatomy is required. Even for seasoned veterans a review of anatomy may be required before less common techniques are performed. A most important principle when performing perineural analgesia is to *start distally in the limb and work proximally* (Figures 10-1 to 10-4). If possible, sequential blocks from distal to proximal should always be used, but in certain circumstances a different strategy can be successful. Sequential blocking requires a fair amount of time, and in certain horses, selective intraarticular or local blocks can be performed without following this “golden rule.” However, in most situations, blocking a large portion of the distal limb at a proximally located site may preclude accurate determination of the source of pain causing lameness and may require an additional visit to perform additional diagnostic procedures.

It is important to test the efficacy of a perineural block before reevaluating the horse's degree of lameness. If any question exists, the block should be repeated rather than assuming deep pain has been abolished, when skin sensitivity persists. If a horse shows *partial* improvement only minutes after injection, an additional few minutes should be allowed for complete analgesia to be achieved before

proceeding with the next block. Alternatively, the block can be repeated. In so doing, the clinician minimizes the potential for misinterpretation and the tendency to ascribe the residual lameness to a “second problem” that does not exist.

During this portion of the examination, we are attempting to eliminate baseline rather than induced lameness, and care must be taken when adopting the practice of “blocking out a positive flexion test” (see Chapter 8). Once baseline lameness has been eliminated, we rarely perform additional flexion tests or attempt to eliminate all induced lameness.

How is the efficacy of the block assessed? Several methods are available, but the following points should be considered. Individual horses react differently to noxious stimuli applied to the skin. Therefore it is helpful to test the contralateral (unblocked) limb to establish the horse's baseline response to the test. Similarly, covering a horse's eye or feigning a few gestures with an instrument (pen tip, hemostatic forceps) without actually contacting the skin can help differentiate between a random or anticipatory response by an apprehensive horse and a true painful response. Positioning oneself on the contralateral side of the horse when testing for sensation also can help in making this determination. The clinician should avoid using sharp instruments that can penetrate the skin and cause hemorrhage, a situation not well understood by a concerned horse owner. Hemostatic forceps, used to pinch the skin, are ideal, because they are blunt and appear to consistently induce an appropriate amount of pain. Forceps are only useful in assessing superficial or skin sensation, however.

Perineural blocks must be assessed for the amelioration of deep and not just superficial pain. To assess whether deep pain in the hoof has been ameliorated after palmar digital analgesia or other techniques, hoof testers can usually be applied with enough force to cause a painful response, even in the most stoic of horses. Physical strength of the operator must be considered. Extreme or hard joint flexion (combined with varus or valgus stress) can be used to assess whether deep pain has been abolished in more proximal locations. In some instances, however, it is impossible to avoid contacting the skin proximal to the site of local anesthetic administration, leading the clinician to assume that the block has not worked. The application of firm digital pressure in the blocked area may be a viable alternative to flexion or manipulation to help avoid these potentially confounding factors.

It is important to understand that the region of the limb that is *actually* desensitized may, in fact, differ from the region the clinician *intended* to desensitize.⁷ Proximal diffusion of local anesthetic solution appears to be the most likely cause, but other, intangible factors may play a role. Using a small volume of local anesthetic solution (1 to 5 mL for most perineural blocks) can minimize but not abolish this phenomenon. To further minimize the potential for diffusion of local anesthetic solution, the horse should be reevaluated no more than 10 minutes after the injection (exceptions apply in certain situations). A recent study using 2 mL of radiopaque contrast medium injected perineurally around the palmar nerves at the level of the proximal sesamoid bones demonstrated proximal diffusion extending 2 to 3 cm within 10 minutes of injection, irrespective of whether horses stood still or walked.⁸

Fig. 10-1 • Blocking strategy in the forelimb: foot to carpus. CMC, Carpometacarpal; DFTS, digital flexor tendon sheath; MC, middle carpal; McIII, third metacarpal bone; MCP, metacarpophalangeal; P3, distal phalanx; PIP, proximal interphalangeal.

Complete analgesia, and thus 100% improvement in lameness score, is the goal when performing diagnostic analgesia, but in many horses this level of pain relief is never achieved. Improvement in degree of lameness greater than 70% to 80% after most perineural or intraarticular

techniques should be considered a positive response in most horses. The quintessential response is that the horse “switches lameness” to the contralateral limb, indicating that now pain arising from the opposite limb is greater than the pain that caused the baseline lameness. However,

Fig. 10-2 • Blocking strategy in the forelimb: antebrachium to shoulder joint. OA, Osteoarthritis.

complete response may not occur, and the clinician must decide when to stop sequential blocks or when the horse has “blocked out.” The clinician hopes for an obvious difference in lameness score when the horse is blocked, but in some horses, serial improvement occurs with each successive block, a situation that makes assessing the primary source of pain difficult.

Incomplete response to local analgesia in some horses may be explained by the fact that chronic pain, particularly deep bone pain, may remain resistant to complete analgesia when perineural techniques are used. For example, horses with laminitis tend to remain lame despite blocking many times at the appropriate level, probably because of neuropathic pain.⁹ Mechanical gait deficits do not improve after diagnostic analgesia because pain is minimal. Horses may continue to show lameness even with pain abolition, a situation that appears to be caused by habit. These horses tend to show mild residual lameness initially, only to warm out of it quickly during examination. Other factors affecting response to diagnostic analgesia include individual variation in neuroanatomy, the intermittent nature of certain lameness conditions, and the inherent difficulty in assessing and abolishing pain in horses with subtle lameness.¹⁰ Articular and subchondral bone lesions may not be desensitized by

intraarticular analgesia, and pain may be more effectively abolished using perineural techniques.

Sensory innervation of joints is complex and involves three classes of neurons that transmit information from four receptor types, each of which has a specific distribution throughout the joint.¹¹⁻¹³ Articular pain can arise from several sources, including the synovium (inflammation, effusion), fibrous joint capsule (increased intraarticular pressure), articular and periarticular ligaments, periosteum, and subchondral bone (injury, osseous vascular engorgement).^{10,12,14,15} Other than small branches in the perichondrium, articular cartilage is devoid of innervation. In osteoarthritic joints, however, erosion channels, formed in the calcified layer of cartilage, are invaded by subchondral vasculature.¹² Putative nociceptive neurotransmitters were identified in these areas, and therefore it is plausible that in horses with advanced osteoarthritis, pain could be emanating from the deep cartilage layers.^{16,17}

On occasion, lameness from an articular lesion abates after perineural analgesia but shows minimal or only partial response after intraarticular analgesia. In some horses, this can be explained by the fact that pain is originating from articular and periarticular tissues.⁸ Subchondral bone pain—caused by maladaptive bone remodeling, cystic or erosive lesions, incomplete fractures, and

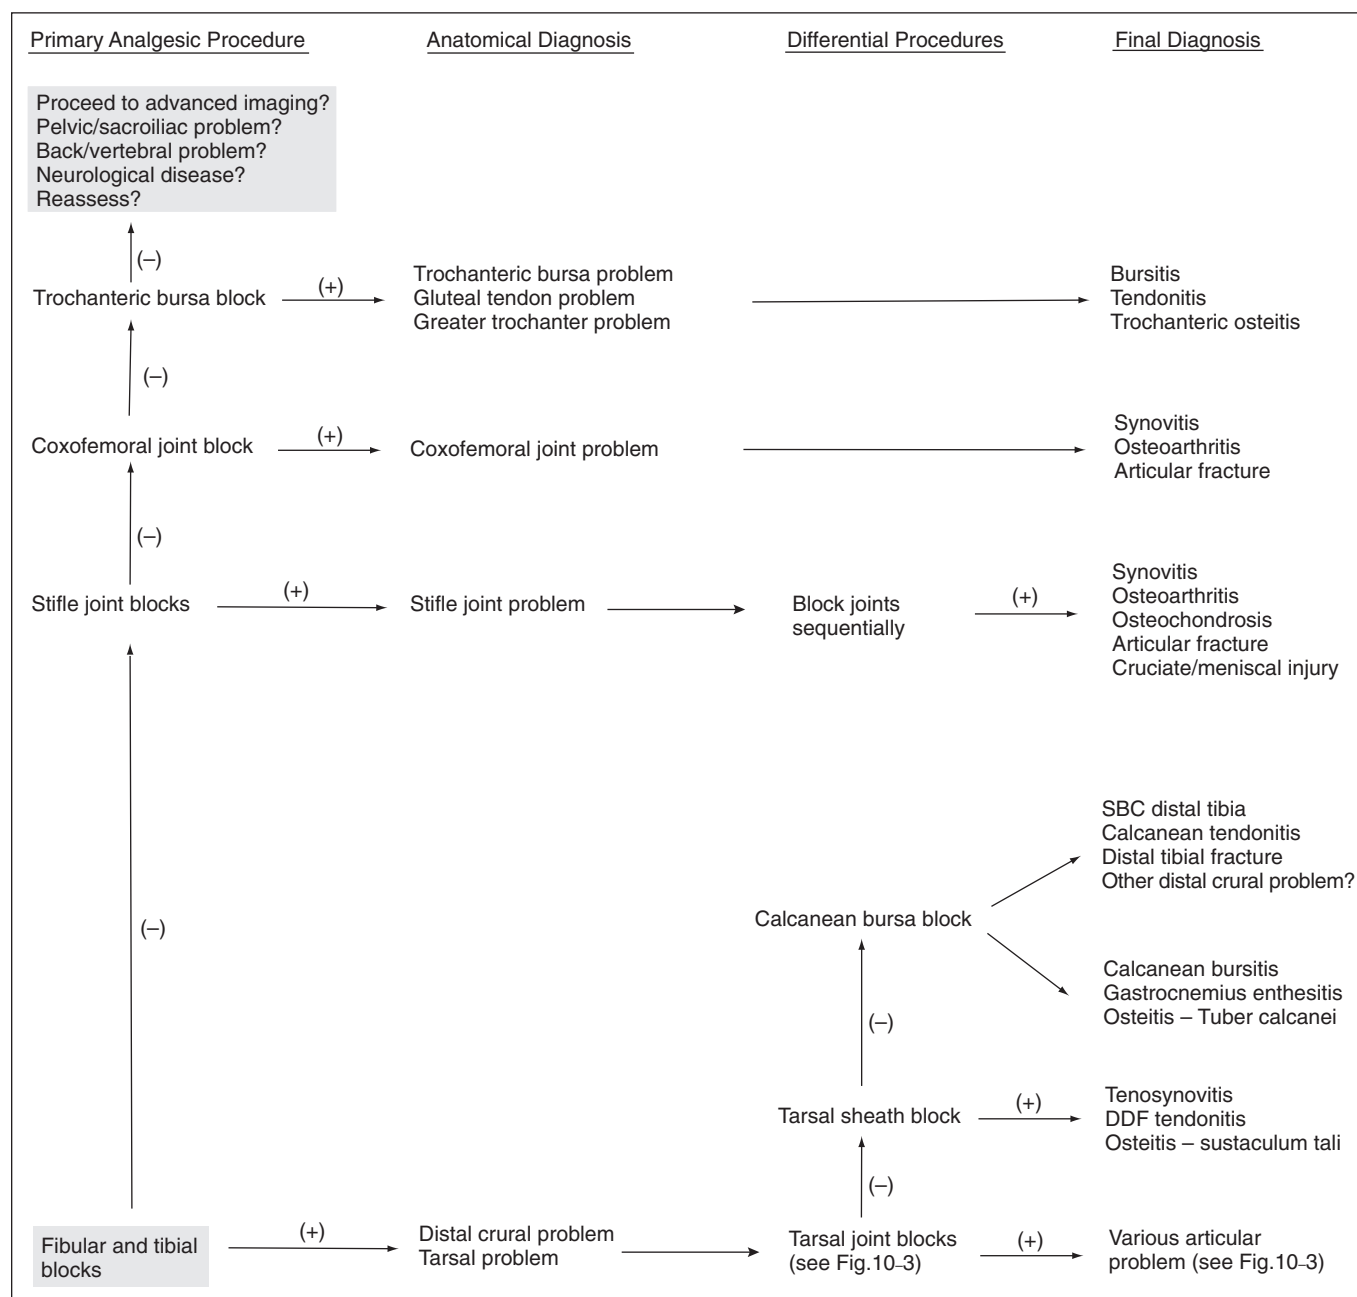

Fig. 10-4 • Blocking strategy in the hindlimb: crus to coxofemoral joint. DDF, Deep digital flexor; SBC, subchondral bone cyst.

osteoarthritis—is inconsistently abolished by intraarticular analgesia. In fact, subchondral bone pain is abolished much more consistently by perineural techniques. Subchondral bone receives innervation from endosteal branches of peripheral nerves that enter the medullary cavity through the nutrient foramen.^{10,11,18,19} Intraarticularly administered local anesthetic solutions may not penetrate subchondral bone sufficiently to completely block these nerves. This shortcoming is presumably even more likely in situations in which the cartilage is intact.

Unfortunately, intraarticular analgesia, although easier to perform, inconsistently abolishes pain from many of the common articular problems. This fact, however, is either overlooked or misunderstood by many practitioners.

Whenever possible, perineural analgesia should be performed, particularly in the distal aspect of the limbs, because this type of analgesia more consistently abolishes pain from all aspects of the joint and surrounding soft tissue structures.

Lameness Is Worse after Diagnostic Analgesia

Two uncommon situations arise when performing diagnostic analgesia. The first occurs during a blocking session. After performing palmar digital analgesia in a horse with forelimb lameness, lameness score may worsen by one or two grades. In fact, lameness may occasionally be considerably worse, prompting concern by the lameness diagnostician. Why? This unusual response occurs most commonly

in horses with proximal, palmar metacarpal pain caused by proximal suspensory desmitis, avulsion fracture of the proximal palmar aspect of the third metacarpal bone (McIII), or proximally located superficial digital flexor tendinitis. Horses normally shorten the cranial phase of the stride to protect a source of pain, a common response by any lame horse. We reason that after palmar digital analgesia a lack of proprioception in the digit prompts the horse to take a somewhat longer stride, increasing the cranial phase. Compared with before the block an exaggerated load causes the horse to display a higher lameness score. Temporary exacerbation of lameness after palmar digital analgesia can be a useful characteristic to help determine the genuine source of pain.

The second situation is more ominous. A horse will occasionally be very lame, sometimes non-weight bearing, once a block wears off. This unusual, but important and sometimes difficult situation occurs when incomplete fractures become separated, displaced, or comminuted. Horses with fractures of the distal phalanx that are incomplete or have healed partially by a fibrous union or those with incomplete fractures of the proximal phalanx appear most at risk. Horses at risk are candidates for imaging before blocking, but in some this complication is unforeseen (see following discussion).

Perception of Diagnostic Analgesia by Laypersons

One of the intangible factors that can complicate the lameness examination is the layperson's perception of diagnostic analgesia or nerve blocking. In many instances the opportunity for an owner or trainer to observe the outcome of diagnostic analgesia provides the concrete evidence that finally convinces him or her of the diagnosis. The classic example is the suspected acute shoulder injury that is actually chronic navicular disease. However, for many reasons, misunderstanding about diagnostic analgesia can lead to frustration for everyone involved. Many laypersons are not fully able to recognize the baseline lameness and therefore may not be capable of seeing that the horse's lameness improves after the block. Another difficulty is trying to explain why lameness in a horse with an articular problem is better after a perineural block but no better when local anesthetic solution is placed directly into a joint. Similarly, many laypersons do not understand why a horse with an articular lameness may "block sound" but does not respond satisfactorily to therapeutic injection. This finding that a horse blocks sound but does not "inject sound" is quite common in young racehorses with subchondral bone pain. Most experienced practitioners have learned to deal with these issues, but the new graduate may need fortitude and ingenuity when explaining the results of diagnostic analgesia.

Role of Chemical Restraint

Whenever possible, use of physical (nose or shoulder twitch) rather than chemical restraint is best when diagnostic analgesia is performed. This is particularly important in horses with low-grade lameness. The analgesic properties of α_2 -agonists (e.g., xylazine, detomidine) and synthetic opiates (e.g., butorphanol) are well recognized and may lead to false-positive results. Ataxia after sedation can complicate lameness interpretation. However, in some horses mild sedation or tranquilization may be necessary

for performance of diagnostic analgesia and may improve the clinician's ability to evaluate the baseline lameness. Acetylpromazine (0.02 to 0.04 mg/kg intravenously) can calm a highly strung horse and facilitate the lameness examination. Extra care must be taken when performing hindlimb procedures, and the safety of everyone involved and the horse must be considered. In horses with moderate or severe lameness, xylazine (0.15 to 0.30 mg/kg intravenously) may not interfere appreciably with lameness interpretation. Similarly, extremely fractious horses can be sedated with an α_2 -agonist, which then is reversed with the prescribed α_2 -antagonist (e.g., yohimbine) before reevaluation. Alternatively, sedation can simply be allowed to wear off before the horse is evaluated, but diffusion of local anesthetic solution may occur or the effect may wear off, both of which may potentially cause misinterpretation of results.

Horse Preparation

Before perineural analgesia is performed, the skin and hair should be cleaned of any gross debris such as mud, bedding, feces, or poultice. Clipping usually is not necessary unless the hair coat is long and prohibits accurate palpation of anatomical landmarks or adequate cleaning of the site. The site should then be scrubbed with an antiseptic, such as povidone-iodine or chlorhexidine, using clean gauze sponges or cotton. If the clinician has any concern about inadvertent penetration of a synovial cavity, a 5-minute aseptic preparation should be performed. This is followed by isopropyl alcohol administration over the site using cotton or gauze sponges.

Aseptic preparation should always be performed before any intrasynovial injection. Considerable debate and variation exists among clinicians regarding the need to clip the hair over the site. Some clinicians always clip the hair, whereas others never do. Still others shave the hair in a small area directly over the injection site. The results of a study indicated no significant difference in the number of postscrub colony-forming units (bacterial flora) between clipped and unclipped skin over the distal interphalangeal (DIP) and carpal joints.²⁰ Nonetheless, we still clip the hair over all proposed intrasynovial injection sites before undertaking a 5-minute aseptic preparation. The only time we deviate from this policy is when we are specifically asked not to clip the hair, a situation that arises in some sports horses actively competing, in claiming horses, or in those being sold.

Similar variation among clinicians exists regarding wearing of sterile latex gloves when performing an intrasynovial injection. However, we recommend wearing sterile gloves during these procedures. Science aside, clipping hair and wearing sterile gloves project a positive impression to all in attendance.

How does, or should, the practitioner attempt perineural or intrasynovial analgesia in a horse with contact or chemical dermatitis (scurf) over the proposed injection site? A superficial wound or abrasion with a localized infection presents a similar quandary. For obvious reasons, these areas are difficult, if not impossible, to clean effectively. If possible, an alternative site, away from the area of dermatitis, should be used. If not, then the procedure should be delayed until the skin condition (or wound) has resolved. In many instances, dermatitis can be treated with topical

medications (medicated sweats such as nitrofurazone-dimethylsulfoxide) for a few days to facilitate resolution of the problem.

Injection Techniques

Perineural injections are typically performed using needles ranging in size from 25 gauge, 1.6 cm ($\frac{5}{8}$ inch) to 20 gauge, 2.5 or 4 cm (1 to 1½ inches). Small needles cause less pain but carry the risk of breaking off within tissues if the horse kicks out or otherwise misbehaves. For this reason, we recommend using 18- or 19-gauge needles for injections or blocks within the proximal metatarsal or plantar tarsal regions. In the distal aspect of the limb the needle is inserted subcutaneously directly over and parallel to the nerve. We generally direct the needle proximally rather than distally, although this portion of the procedure differs among clinicians. One of the Editors (SJD) always inserts the needle distally; if a fractious horse throws the limb to the ground the needle is more likely to stay in situ, and the remainder of the procedure may be completed with the limb on the ground. Directing the needle distally also ensures more distal placement of the local anesthetic solution, which may be important at distal sites. The needle is inserted before the syringe is attached. To avoid excessive manipulation once the needle is inserted, a slip-type syringe hub is preferred. Syringes with screw-on hubs can be difficult to attach, requiring additional manipulation in a sometimes fractious horse, and are not generally used. However, when dense tissue requires that additional force be used for injection, the seal between the hub and the needle can be broken, a complication minimized by using a screw-on hub (see the following discussion of [lateral palmar block](#)).

Volume of local anesthetic solution varies, but for a majority of blocks in the distal limb, 1 to 5 mL is injected at each site. Larger volumes are used to perform the median and ulnar or fibular (peroneal) and tibial techniques and when infiltrating the proximal palmar (plantar) metacarpal (metatarsal) region. After injection, we briefly massage the sites with gauze sponges or clean cotton soaked in alcohol. Skin sensation and deep pain are assessed 5 to 10 minutes after injection. More time is allowed under certain circumstances (see specific comments throughout the chapter). At the completion of the examination an alcohol wrap should be applied to minimize swelling, a common sequela resulting from local irritation and bleeding from nearby vessels.

For “ring” blocks, circumferential subcutaneous infiltration of local anesthetic solution, and other local or regional infiltration techniques, we most commonly use 20- to 22-gauge, 4-cm needles. For performance of a ring block, the needle is inserted perpendicular to the long axis of the limb, and local anesthetic solution is injected as the needle is advanced, leaving a clearly visible wheal or subcutaneous bleb in most locations. The needle then is reinserted at the leading edge of this wheal, a practice that minimizes the number of injections and the horse’s discomfort. However, most horses object to needle insertion even when it is performed well within the bleb. The injection is continued around the limb in this manner. For most ring blocks in the distal limb, 10 to 15 mL of local anesthetic solution is used, but larger volumes may be preferred for surgical procedures. Ring blocks can be done as a

substitute for or in combination with perineural injections (see the specific blocking techniques discussed in the chapter). However, simply placing local anesthetic solution in a subcutaneous location is not a substitute for the preferred approach, direct perineural injection.

To block a local area such as a splint or curb, the needle is typically inserted in one or two locations, and local anesthetic solution is deposited in a fan-shaped pattern. As with the perineural analgesia, the sites are massaged briefly and the horse is reevaluated in 5 to 10 minutes.

Intrasynovial injections typically are performed using needles ranging in size from 22 gauge, 2.5 cm to 18 gauge, 4 cm. If marked effusion is present, drainage of synovial fluid is advised, either by allowing the fluid to drip from the hub of the needle or by aspirating with a sterile syringe before proceeding with injection. We prefer the former procedure unless fluid analysis is necessary. The manipulation required to attach the syringe may cause the horse discomfort and potentially dislodge the needle but if successful may hasten withdrawal of synovial fluid. Brief evaluation of the color and viscosity of synovial fluid can shed some light on the disease process within and is expected practice among most racehorse trainers. Volume of local anesthetic solution varies considerably between synovial cavities, but the clinician should keep in mind that small volumes might contribute to a false-negative result. False-negative results are common in horses with severe osteoarthritis, and larger volumes of local anesthetic solution should be used. We routinely spray or wipe antiseptic solution over the injection site. After the examination a light bandage is applied over the injection sites from the metacarpophalangeal or metatarsophalangeal joint, distally. Initial reevaluation is done 5 to 10 minutes after injection. Additional evaluations may be necessary depending on the response during the initial time period. General practice is to have the horse walked in hand or with a rider after perineural or intrasynovial analgesia is administered, a procedure thought to hasten distribution of local anesthetic solution and potentially improve success. Excessive diffusion of local anesthetic solution is a potential drawback to this practice, particularly with techniques such as DIP or middle carpal analgesia (see the following discussion), although it would be a complication difficult to quantify.

Another issue to consider when performing diagnostic analgesia is whether riding or driving a horse after blocks have been performed is safe. In general, riding on the flat or driving a horse at slow speed after any of the common blocks have been performed is safe. Stumbling or knuckling can be a concern after upper limb perineural techniques, such as the median and ulnar and fibular (peroneal) and tibial techniques. Common sense should prevail, however, with regard to the horse and rider negotiating fences or performing at high speed. Horses at risk for lameness from stress or incomplete fracture are candidates for imaging before evaluation at speed after diagnostic analgesic techniques have been performed. Moreover, horses suspected of having incomplete fractures but with negative or equivocal radiological findings may best be managed conservatively without use of analgesic techniques and should undergo either follow-up radiographic examination in 10 to 14 days or scintigraphic examination.

PERINEURAL ANALGESIA IN THE FORELIMB

Palmar Digital Analgesia

Palmar digital analgesia (or palmar digital block) is the most common diagnostic analgesic procedure performed. The medial and lateral digital neurovascular bundles, consisting, in a dorsal to palmar direction, of the digital vein, artery, and nerve, course in an abaxial location to the digital flexor tendons. With the exception of small breeds or draft horses with remarkably long-haired pasterns (feathers), the palmar digital nerve is easily palpable between the proximal sesamoid bones and the cartilages of the foot. The palmar digital block can be performed with the horse in a standing position or with the limb held off the ground. We prefer the latter. If held by an assistant, the limb should be grasped in the midmetacarpal region, with the fetlock and digit hanging in neutral position. The palmar digital nerve is easily palpated in this extended position on the lateral aspect of the deep digital flexor tendon (DDFT). Alternatively, the clinician performing the block can hold the limb, a technique that requires practice. The clinician can stand facing backward with a hand grasping the midpastern region or can stand behind the limb and clutch the hoof between both legs.

A 25-gauge, 1.6-cm needle is inserted subcutaneously, directly over the nerve, just proximal to the cartilages of the foot (Figure 10-5). One of us (LHB) directs the needle in a distal direction, whereas the other (MWR) directs the needle in a proximal direction to avoid deeper penetration or laceration of digital vessels if the horse withdraws the limb. Alternatively, a 22-gauge, 4-cm needle can be inserted on the palmar midline in the midpastern region, and local anesthetic solution is then infiltrated in a V-shaped pattern. This modification of the palmar digital block is quite difficult to perform in the hindlimb but when done in the forelimb provides maximal analgesia to the bulbs of the heel and minimizes the potential for depositing local anesthetic solution dorsal to the nerve. Loss of skin sensation in the midline between the bulbs of the heels should be assessed, because this area seems most recalcitrant to palmar digital analgesia. Deep pain is assessed using hoof testers. However, if skin sensation persists, it is still worth reevaluating lameness, because in some horses deep pain and lameness may be abolished despite the persistence of skin sensation.

Traditionally the palmar digital block was felt consistently to desensitize only the palmar (plantar) one third to one half of the foot.²¹ However, in clinical practice, this block desensitizes 70% to 80% of the foot. Most of the DIP joint is affected, with the exception of the proximodorsal aspect. Horses with fractures of the extensor process of the distal phalanx or injury of a collateral ligament of the DIP joint may show partial improvement after palmar digital analgesia, however. Our clinical observations have been substantiated in a recent study. Setscrews were placed near the medial and lateral aspects of the toe to simulate pain from the sole. Lameness in these horses was abolished using palmar digital analgesia performed just proximal to the heel bulbs.²²

Classically, most horses that responded positively to palmar digital analgesia were thought to have navicular syndrome, but this block desensitizes many lameness conditions within and outside the hoof capsule (Table 10-1).

This is an important and common misconception. Lameness in horses with proximal interphalangeal joint pain, midsagittal fracture of the proximal phalanx, or other conditions involving the fetlock joints can be abolished using palmar digital analgesia.^{7,23} Although using small volumes of local anesthetic solution and performing the block just above the cartilages of the foot may help to minimize the area of analgesia, these procedures do not prevent inadvertent diagnosis in some horses. Diffusion of local anesthetic solution is the most likely explanation, and even a small volume can readily spread in a proximal direction, but the normal anatomy of the digit prevents distal placement of local anesthetic solution (Figure 10-6).

The concept that palmar digital analgesia abolishes lameness in an area considerably more than the palmar (plantar) one third of the foot appears to be difficult for many to accept. Although results of studies are widely published and this finding has been emphasized at international meetings, most veterinary students still graduate today armed with this common misconception. Diffusion of local anesthetic solution easily explains why lameness conditions in the proximal aspect of the pastern or fetlock regions are desensitized by palmar digital analgesia. But what about the innervation of the hoof itself? Skeptics should consider the anatomy of the palmar digital nerve. Most practitioners have severed the palmar digital nerve while performing neurectomy. Can the clinicians recall any instance of having identified a large dorsal branch, or for that matter, any branching of the nerve at all? The lack of nerve branches in the midpastern region is circumstantial evidence that important innervation to the structures located dorsally within the hoof capsule occurs farther proximally (ill-defined dorsal branches) or after the nerve courses deep to the cartilages of the foot. It makes little sense that ill-defined dorsal branches would innervate the dorsal two thirds of the foot, leaving the robust palmar digital nerve to innervate only the palmar one third. When carefully dissected the palmar digital nerves can be seen branching extensively deep to the cartilages of the foot, sending branches dorsally to innervate the dorsal portions of the foot.

Accurately quantifying the contribution of the palmar digital nerve to the innervation of the foot or, for that matter, the exact percentage of structures desensitized by palmar digital analgesia may be impossible. Clinical experience will undoubtedly convince practitioners of the broad nature of palmar digital analgesia. Finally, it is imperative to develop expertise in diagnostic imaging of the entire digit, because the many lameness conditions affected by palmar digital analgesia require detective-like differential diagnostic skills.

Midpastern Ring Block

Traditionally the diagnostic blocks performed after palmar digital analgesia are the basisesamoid or abaxial sesamoid techniques. The basisesamoid block provides little additional information compared with palmar digital analgesia, unless, of course, the dorsal branch, originating from the digital nerve at the level of the proximal sesamoid bones, is blocked. If, however, the dorsal branch is blocked, then the basisesamoid block is in reality an abaxial sesamoid block. For this reason, we rarely perform the basisesamoid block. When performing the abaxial sesamoid

Fig. 10-5 • A, Palmarolateral view of the distal aspect of the limb showing site for needle penetration for palmar (plantar) digital analgesia (a). The clinician directs the needle as shown or in a proximal direction. The palmar (plantar) digital nerve is blocked more proximally at the level of the abaxial surface of the proximal sesamoid bone (b). At this level the palmar (plantar) digital nerves and dorsal branches are both blocked. **B,** Dorsolateral view of the distal aspect of the limb demonstrating needle positions for palmar (plantar) digital analgesia (a) with an additional dorsally directed subcutaneous ring block to desensitize the dorsal aspect of the pastern region and foot (b). A block at the base of the proximal sesamoid bone (c) likely desensitizes the palmar (plantar) digital nerves and dorsal branches of the digital nerve (note close association of both branches to the site of the block) and provides the same region of analgesia as does the palmar digital block with the dorsal ring, or the abaxial sesamoid block. **C,** Alternative technique used for the palmar digital nerve block. The clinician inserts the needle on the palmar midline and places a line of local anesthetic solution in a proximal dorsal direction to the level of each of the medial and lateral palmar nerves in an approximately V-shaped pattern. This technique confines local anesthetic solution to the palmar aspect of the limb. This blocking technique is difficult to perform in the hindlimb.

TABLE 10-1

technique in racehorses, or, for that matter, in any sport horse with a propensity to develop lameness of the metacarpophalangeal or metatarsophalangeal joints, the veterinarian runs the risk of an additional misdiagnosis. When local anesthetic solution is deposited in a location abaxial to the proximal sesamoid bones, pain from the metacarpophalangeal or metatarsophalangeal joints can be inadvertently blocked, explained most likely because of diffusion of local anesthetic solution, leading the clinician to assume the horse has a problem in the foot or digit, but in reality the pain originated from these joints. For these reasons, we prefer to use a blocking sequence as follows: palmar digital nerve, followed by a dorsally directed subcutaneous ring block, followed by the low palmar or plantar block.

The midpastern ring block affects the dorsal branches of the digital nerves and desensitizes any remaining areas of the foot and pastern region that were not affected by palmar digital analgesia. In most horses this includes the dorsal 20% of the foot (dorsal laminar and extensor process regions of the distal phalanx) and the dorsal pastern region (dorsal aspects of the middle phalanx and proximal interphalangeal joint, and distal portions of the proximal phalanx). Although desirable, performing the dorsal ring block just above the cartilages of the foot usually is not possible. Instead the block is performed at the level of the midpastern region.

A 20- to 22-gauge, 4-cm needle is used to deposit subcutaneously 10 to 12 mL of local anesthetic solution, beginning near the injection site used for palmar digital analgesia

over the lateral neurovascular bundle and continuing dorsally and medially, ending over the medial neurovascular bundle (see Figure 10-5). Resistance to needle advancement and injection of local anesthetic solution will invariably be encountered dorsally, if the block is done just proximal to the coronary band, because of the dense tissue (proximal interphalangeal joint capsule, extensor branches of the suspensory ligament, and extensor tendons). Performing the block in the midpastern region minimizes this problem and mitigates the potential for inadvertent penetration of the proximal interphalangeal joint.

Abaxial Sesamoid Block

Desensitizing the medial and lateral palmar nerves at the level of the proximal sesamoid bones is commonly referred to as the *abaxial sesamoid block* but may provide the same information as the *basisesamoid block*, if the dorsal branch of the palmar digital nerve is blocked. To avoid redundancy, we rarely perform the *basisesamoid* technique before progressing to the *abaxial sesamoid block* (see previous comments). A block done at this level essentially provides analgesia of the entire digit, because the block is performed at the level of or just proximal to the origin of the dorsal branch of the palmar digital nerve. Response to this block may vary, however. Some horses retain skin sensation in the dorsoproximal aspect of the pastern region. In others, pain arising from lesions involving the fetlock joint or periarticular tissues is abolished. In part, these phenomena can be explained by proximal diffusion

Fig. 10-6 • Radiograph showing palmar digital analgesia performed with positive contrast material. The clinician performed palmar digital analgesia as far distal as possible, but the injection site is still at the level of the proximal interphalangeal joint, explaining why palmar digital analgesia desensitizes most of the foot and the pastern region in some horses.

of local anesthetic solution, affecting the palmar digital nerves proximal to the fetlock joint. Branches of the palmar digital nerves supplying the proximal sesamoid bones, the sesamoidean nerves, could easily be blocked using an analgesic technique in this abaxial position.²⁴ One of the Editors (SJD) regularly performs palmar nerve blocks at the base of the proximal sesamoid bones as a first block if, on the basis of clinical examination, it is considered unlikely that the horse has foot-related pain and there is also no evidence of likely fetlock joint pain.

The abaxial sesamoid block can be performed in the standing horse or with the limb held by the clinician or an assistant. The assistant grasps the foot, facing forward. The assistant should be warned that a fractious horse may kick backwards with the limb, so he or she should stand slightly to one side, outside the plane of the limb. The palmar digital nerve can easily be palpated over the rigid proximal sesamoid bones and in fact is in its most superficial position in this location. A 25-gauge, 1.6-cm needle is directed in a proximal or distal direction and typically 1 to 3 mL of local anesthetic solution are used for each of the medial and lateral injections. Deep pain is assessed by hard flexion of the interphalangeal joints. False-negative or delayed results can arise because of deposition of local anesthetic solution outside the fascia that surrounds the neurovascular bundle.⁸

Low Palmar Analgesia

Analgesia of the metacarpophalangeal joint region and distal aspect of the limb is induced using the low palmar

block or low palmar analgesia (low four-point). This technique blocks the medial and lateral palmar nerves and the medial and lateral palmar metacarpal nerves. In the forelimb a subcutaneous, dorsally directed ring block and block of the dorsal branch of the ulnar nerve completely abolishes skin sensation. Disagreement exists about whether abolishing skin sensation is necessary when performing perineural techniques. Abolition of skin sensation independently from nerves contributing to deep pain sensation, as in the case of the low palmar technique, does not necessarily mean deep pain is abolished, which is particularly relevant when a nerve responsible for skin sensation is blocked. When using these techniques for diagnostic purposes, it may be best to avoid blocking nerves that contribute only skin sensation, thus minimizing the number of needle insertions. For therapeutic interventions, however, these nerves need to be blocked.

The low palmar block is performed at the level of the distal end (bell or button) of the second and fourth metacarpal bones (splint bones), with the limb in a standing position or held off the ground (Figure 10-7). A 20- or 22-gauge needle is used to inject 1.5 to 5 mL of local anesthetic solution at each injection site. To block the palmar metacarpal nerves, the needle is inserted perpendicular to the skin, just distal to the end of the splint bones, to a depth of 1 to 2 cm. It is important to deposit local anesthetic solution deep in the injection site, rather than simply in a subcutaneous location. While local anesthetic solution is continuously injected, the needle is slowly withdrawn, leaving a visible bleb in the subcutaneous space. To block the medial and lateral palmar nerves, the needle is inserted subcutaneously, in the palmar aspect of the space between the suspensory ligament and DDFT at the level of or slightly more proximal to the distal end of the splint bone. To improve the accuracy of the injection, using a fan-shaped injection technique is helpful. If the digital flexor tendon sheath (DFTS) is distended, the injections must be performed more proximally. Inadvertent penetration of the DFTS is possible even if it is not distended, so careful skin preparation is mandatory. To complete this block, local anesthetic solution is placed in the subcutaneous tissues from the bleb at the distal end of the splint bone to the dorsal midline. One of the Editors (SJD) does not do this last step.

An alternative technique to abolish pain associated with maladaptive or nonadaptive bone remodeling or other causes of subchondral bone pain of the distal aspect of the McIII is to block the lateral and medial palmar metacarpal nerves separately from the lateral and medial palmar nerves. In some horses suspected of having this injury, use of abbreviated low palmar analgesia will avoid additional injections of local anesthetic solution. With this technique the lateral or medial palmar metacarpal nerve, or both, can be blocked individually or together, and the horse's gait assessed. In many horses with this cause of lameness, contralateral forelimb lameness will then be seen. If lameness does not abate, the clinician then completes low palmar analgesia using the technique described previously (see the following discussion).

Alternatively, some clinicians prefer to use a longer needle first to deposit local anesthetic solution over the palmar metacarpal (metatarsal) nerves. The needle is then pushed subcutaneously to deposit local anesthetic solution over the palmar nerves (see Figure 10-7). When this

Fig. 10-7 • A, This lateral view shows needles positioned for a low palmar (plantar) nerve block. The clinician inserts a needle (a) just distal to the distal aspect of the fourth metacarpal or metatarsal bone and directs it axially to block the lateral palmar (plantar) metacarpal (metatarsal) nerve. The clinician then inserts a needle (b) between the suspensory ligament (SL) and deep digital flexor tendon (DDFT) to block the lateral palmar (plantar) nerve. The clinician repeats the two injections on the medial side. A subcutaneous ring block from the first injection site around to the dorsal midline (c) completely abolishes skin sensation. **B,** Transverse view of the distal left metacarpal region demonstrating an alternative technique for low palmar (plantar) analgesia. The clinician inserts a needle (a) in a lateral-to-medial direction between the DDFT and the SL to block the lateral and medial palmar (plantar) nerves. The palmar (plantar) metacarpal (metatarsal) nerves are blocked as depicted in **A** (not shown in this diagram), which also shows the subcutaneous ring block. The clinician inserts a needle (b) in a lateral-to-medial direction dorsal to the digital extensor tendons to block the dorsal metatarsal nerves of the hindlimb.

modification is performed, incompletely blocking the palmar metacarpal (metatarsal) nerves or lacerating the digital vessels is possible. The lateral and medial palmar nerves can be blocked using only the lateral injection site by advancing the needle in a medial direction, palmar to the DDFT. Although each of these modifications may theoretically decrease the number of injections needed to perform this technique, they have the disadvantages of potential hemorrhage and incomplete analgesia.

High Palmar Block

To provide analgesia to the metacarpal region, the high palmar block (high four-point, subcarpal block) is the most common technique, but a modified block (lateral palmar or Wheat block) can be performed. Inadvertent penetration of the carpometacarpal joint is a potential complication with the high palmar block. A similar complication can occur in the hindlimb but is less frequent (see the following discussion). Inadvertent penetration of the carpometacarpal joint occurred in 17% of specimens, in which a conventional high palmar block was performed, because of extensive distopalmar outpouchings (Figures 10-8 and 10-9). However, when the high palmar block was performed within 2.5 cm of the carpometacarpal joint, inadvertent penetration of this joint occurred in 67% of specimens. The carpometacarpal joint always communicates with the

middle carpal joint, and therefore penetration of the carpometacarpal joint during high palmar analgesia would lead the clinician to diagnose a metacarpal problem, when in reality the authentic lameness condition exists in the carpus. Moving the injection site in a distal direction decreases the possibility of entering the carpometacarpal joint but also narrows the scope of the technique and may result in a false-negative response in a horse with proximal suspensory desmitis. Two ways around this likely complication are these: first, the clinician could perform middle carpal analgesia before performing high palmar analgesia; second, the clinician could perform a lateral palmar block in lieu of the conventional high palmar technique. In an experimental study, the carpal joints were unlikely to be entered inadvertently during performance of the lateral palmar block, although in every specimen, local anesthetic solution would have entered the carpal canal.²⁵ Unless the clinician is familiar with the lateral palmar block, the most straightforward approach to reduce the possibility of misdiagnosis in this region is to perform middle carpal analgesia before proceeding to the high palmar block. When local anesthetic solution is placed in the middle carpal joint, not only is the carpometacarpal joint blocked, but also the possibility exists of providing local analgesia to the proximal palmar metacarpal region. With this approach, abolishing pain associated with proximal suspensory attachment

Fig. 10-8 • Positive contrast arthrogram of the middle carpal (*mc*) and carpometacarpal (*cmc*) joints (dorsal is to the right). Contrast material injected into the middle carpal joint flows freely distally into the carpometacarpal joint and fills the extensive distopalmar outpouchings of the joint (arrow).

Fig. 10-9 • Liquid acrylic injected into the middle carpal joint and allowed to harden created this specimen showing the lateral (*A*) and medial (*B*) distopalmar outpouchings of the carpometacarpal joint. Secondary finger-like outpouchings ramify in the proximal palmar metacarpal region.

Fig. 10-10 • Transverse section of the proximal metacarpal region just distal to the carpometacarpal joint after latex injection into the middle carpal joint showing primary and secondary distopalmar outpouchings of the carpometacarpal joint (dark areas, arrows) interdigitating with the proximal aspect of the suspensory ligament (dorsal is up; lateral is left). This anatomical arrangement explains inadvertent analgesia of the carpus and proximal palmar metacarpal region during high palmar and middle carpal analgesia, respectively. *McIII*, Third metacarpal bone.

avulsion injury (desmitis, fracture), stress remodeling, and longitudinal fracture is possible (see Chapter 37). The palmar metacarpal nerves and suspensory branches from the lateral palmar nerve are closely associated with the distopalmar outpouchings of the carpometacarpal joint, and diffusion of local anesthetic solution from this area could explain in part this clinical finding (Figure 10-10).

It is important for the clinician to understand that interpretation of analgesic techniques in the proximal palmar metacarpal region or carpus can be somewhat complex. Correct diagnosis is always the key, and comprehensive evaluation using multiple imaging modalities is a must in differentiating lameness in this region. From the clinical perspective, one is more likely to assume incorrectly that one is dealing with a carpal problem when the authentic lameness condition resides in the proximal palmar metacarpal region than vice versa. Numerous techniques are used to perform high palmar analgesia; some provide partial and others provide complete analgesia to the metacarpal region. For complete analgesia, blocking the following nerves is necessary: the medial and lateral palmar nerves, the medial and lateral palmar metacarpal nerves, the suspensory branches, and nerves providing skin sensation along the dorsum (dorsal branch of ulnar nerve and musculocutaneous nerve). To block these nerves effectively, one must use a site close to the carpometacarpal joint, at the level where the splint bones begin to taper (Figure 10-11). If the block is done at a lower level, the region of the suspensory attachment will be missed. A 20- or 22-gauge needle at least 2.5 cm long is necessary to reach the palmar metacarpal nerves in this location. The needle is inserted axial to the splint bones just abaxial to the suspensory ligament and then guided to the palmar

Fig. 10-11 • Transverse view of the left metacarpal region showing the technique for high palmar analgesia. The clinician inserts a needle (a) axial to each second and fourth metacarpal bone and uses two separate injections (b) to block the medial and lateral palmar nerves. The location of the high palmar technique appears in the lateral view (inset).

cortex of the McIII. Five milliliters of local anesthetic solution are deposited, first deep within the tissues, and continued as the needle is withdrawn, ending with a bleb in the subcutaneous tissues. To block the medial and lateral palmar nerves between the suspensory ligament and DDFT, a smaller-gauge needle can be used to deposit 3 to 5 mL of local anesthetic solution at each of two sites. To complete this block, a circumferential subcutaneous ring block is performed to abolish skin sensation dorsally. Alternatively, the subcutaneous nerves can be blocked on either side of the common digital extensor (CDE) tendon, but small zones of sensation may persist when this technique is used. It is only necessary to complete the dorsal portion of this block to provide complete analgesia when performing procedures in the dorsal metacarpal region, such as laceration repair or standing osteostixis.

A modification of the high palmar block is performed by locally infiltrating the suspensory origin from a lateral injection site in a fan-shaped pattern. This procedure, along with one specifically to block the medial and lateral palmar metacarpal nerves, improves specificity of this complex block, because pain from only a limited number of structures is eliminated. The medial and lateral palmar nerves can also be blocked from a single lateral injection site. One of the Editors (SJD) regularly blocks just the palmar metacarpal nerves (using only 2 to 3 mL of local anesthetic solution per site) and only adds perineural analgesia of the palmar nerves if the first block is negative, in order to facilitate differentiation of suspensory ligament or McIII pain from pain arising from the more palmar soft tissue structures. A dorsal ring block is never used.

Lateral Palmar Block

An alternative method of providing analgesia to the metacarpal region is to perform what is known as the *lateral*

palmar (high two-point) or *Wheat block*.²⁶ For complete analgesia, however, combining this block with an independent injection over the medial palmar nerve and with a dorsal subcutaneous ring block is necessary. Originally proposed as an alternative method for analgesia of the suspensory ligament origin, this technique involves blocking the lateral palmar nerve just distal to the accessory carpal bone (Figure 10-12). The lateral palmar nerve is formed as the median and deep ulnar nerves join, proximal to the accessory carpal bone (see Figure 10-12).²⁷ At the level of the block, just distal to the accessory carpal bone, the lateral palmar nerve is blocked before it branches to form the medial and lateral palmar metacarpal nerves and the suspensory branches and continues distally (see Figure 10-12). The high two-point block is completed with the separate but concurrent block of the medial palmar nerve.

This technique has at least three advantages compared with conventional high palmar analgesia. Inadvertently penetrating the distopalmar outpouchings of the carpometacarpal joint is virtually impossible, although local anesthetic solution will likely enter the carpal canal.²⁵ Lateral palmar analgesia requires fewer needle penetrations than does conventional high palmar analgesia. Finally, only a small volume of local anesthetic solution is necessary to desensitize a number of nerves and the origin of the suspensory ligament. Pain associated with the carpal canal is abolished, however, and can be present without palpable effusion.

The lateral palmar block can be performed in the standing position or with the limb held off the ground, with the carpus in 90 degrees of flexion. The nerve cannot be palpated because it courses in the accessorial-metacarpal ligament, dense connective tissue distal to the accessory carpal bone. A 25-gauge, 1.6-cm needle is inserted to the hub, perpendicular to the skin, just distal to the accessory carpal bone, and 5 mL of local anesthetic solution are deposited within this dense tissue. Injection can be difficult to perform, and breaking the seal between the needle and syringe is common, so a screw-type hub should be used. The medial palmar nerve is then blocked as described previously. If desired, a dorsal, circumferential subcutaneous ring block provides complete analgesia to the dorsum. An alternative technique for lateral palmar nerve block has recently been described.²⁸ The primary advantage of this technique is that it mitigates the risk of inadvertent penetration of the carpal synovial sheath (carpal canal). The block is performed with the limb in extension. The primary landmark is a palpable groove in the flexor retinaculum just dorsal to its insertion on the palmaromedial aspect of the accessory carpal bone. A 1.5-cm, 25-gauge needle is inserted in the distal third of the groove in a mediolateral direction, and when contact is made with the medial surface of the accessory carpal bone, local anesthetic solution is injected. However, it is quite easy for the needle to hit the nerve, which results in the horse striking out, and a difficult horse may become even more fractious to block.

Median, Ulnar, and Medial Cutaneous Antebrachial Blocks

Analgesia of the distal aspect of the antebrachium and carpus can be induced by blocking the median, ulnar,

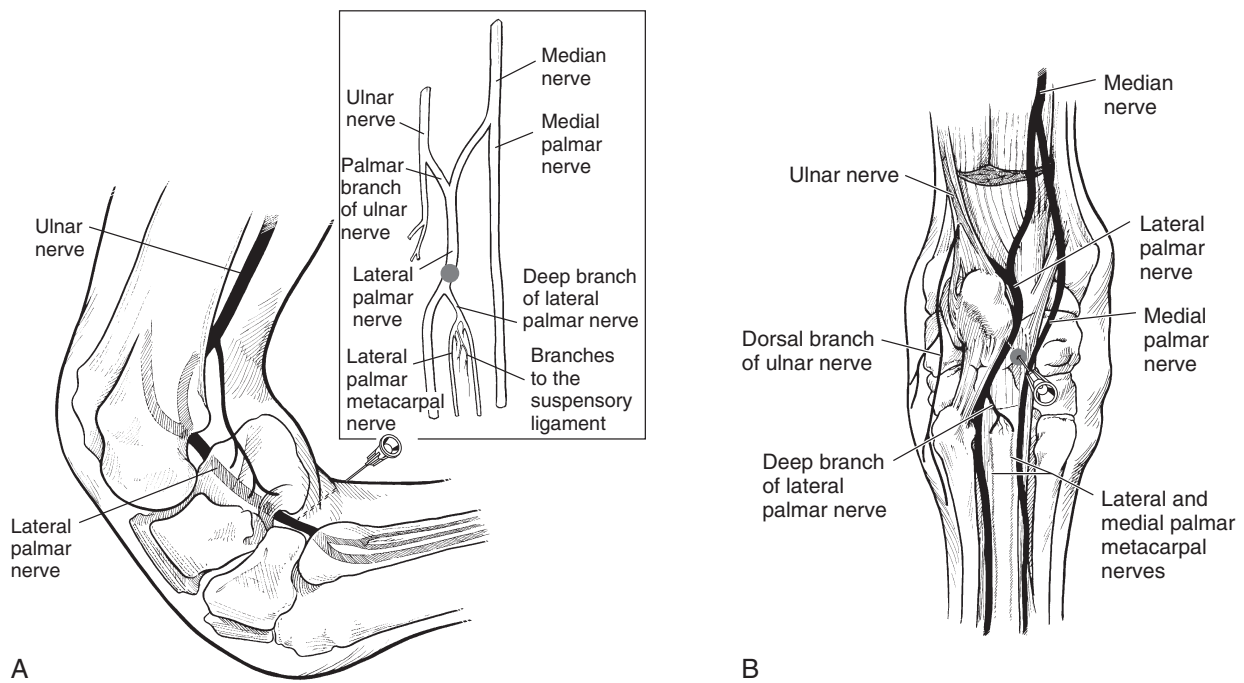

Fig. 10-12 • A, This diagram of the left carpus in a flexed position shows the location of the lateral palmar nerve block and parent nerves (*inset*) contributing to the origin of the lateral palmar and other important nerves. **B,** Palmar view of the limb showing nerves in situ and the site for needle penetration for lateral palmar nerve block.

and medial cutaneous antebrachial (musculocutaneous) nerves.²¹ Because the last nerve supplies only skin sensation, for diagnostic purposes it does not need to be included in the technique. In our practices these blocks are most commonly performed to facilitate lavage of the carpal joints or carpal canal or to perform regional limb perfusion of antibiotics in standing horses. We generally default to intrasynovial analgesia in these structures, however. However, one of us (MWR) has recently evaluated several horses with subchondral bone pain in the middle carpal joint in which intraarticular carpal analgesia failed to abolish clinical signs of pain. Lameness was abolished using the median and ulnar blocks. One Editor (SJD) finds these blocks extremely valuable in horses that do not respond to subcarpal or intraarticular carpal analgesia and employs median and ulnar blocks routinely. Although the median and ulnar blocks remain infrequently used in the United States, perhaps they should be considered routine. Median, ulnar, and medial cutaneous antebrachial nerve blocks are useful in diagnosing subchondral carpal bone pain or lameness involving the carpal canal. Although the prevalence of lameness in the distal aspect of the antebrachium is low, these blocks can be used to diagnose distal radial bone cysts or enthesitis at the origin of the accessory ligament of the superficial digital flexor tendon (SDFT) (superior check ligament). These blocks can be used to eliminate the entire distal aspect of the limb as a potential source of pain. Alternatively, these blocks can be used alone to eliminate pain distal to the injection site, or the median and ulnar nerves can be blocked independently to improve specificity of the technique.

The ulnar nerve is blocked about 10 cm proximal to the accessory carpal bone on the caudal aspect of the antebrachium (Figure 10-13). A 20- or 22-gauge, 4-cm needle is

inserted to the hub, perpendicular to the skin, in the groove between the flexor carpi ulnaris and the ulnaris lateralis muscles. Needle contact with the ulnar nerve may cause the horse to strike forward.⁵ Ten milliliters of local anesthetic solution are injected as the needle is slowly withdrawn. Skin sensitivity along the lateral aspect of the limb from the carpus to the metacarpophalangeal joint will be eliminated.²¹

The median nerve is blocked 5 cm distal to the cubital (elbow) joint on the medial aspect of the antebrachium. At this level, the nerve lies along the caudal aspect of the radius, just cranial to the flexor carpi radialis muscle. A 20- or 22-gauge, 4-cm needle is inserted into the hub, in a lateral direction, along the caudal aspect of the radius, just distal to the superficial pectoral muscle, and 10 mL of local anesthetic solution are used (see Figure 10-13). Rarely in large horses, a 9-cm (3½-inch) spinal needle may be necessary to reach the median nerve. Often the needle hits the median nerve, a useful indicator that the tip is in the proper location.⁵ In any event the needle should be kept close to or against the caudal cortex of the radius to avoid inadvertent puncture of the median artery or vein, which lies caudal to the nerve.^{21,27} However, inadvertent puncture determines that the needle is close to the correct site and is highly unlikely to cause any adverse reaction. To facilitate these deep injections, the skin can be first desensitized by using a small volume of local anesthetic solution. A more distal injection site for the median nerve may eliminate the possibility of inadvertently eliminating elbow joint pain using the suggested approach.⁵

Finally (for therapeutic applications), to block the cranial and caudal branches of the medial cutaneous antebrachial (musculocutaneous) nerve, 3 mL of local anesthetic solution are injected, subcutaneously, on the cranial

Fig. 10-13 • A, This caudal view of the left antebrachium shows the sites of needle insertion for the median and ulnar nerve blocks. A needle placed between the ulnar lateral and flexor carpi ulnaris muscles (*a*), about 10 cm proximal to the accessory carpal bone, blocks the ulnar nerve. A needle inserted along the caudal aspect of the radius about 10 cm distal to the elbow joint (*b*) blocks the median nerve. The inset shows the orientation between the radius, median artery, vein, and nerve at the site of needle insertion (*b*) and shows the orientation of the needle for the ulnar nerve block (*a*), which is performed distally. **B,** This medial view of the proximal left antebrachium shows the technique for a musculocutaneous nerve block. The nerve is blocked as it crosses the lacertus fibrosus on the cranial aspect of the proximal antebrachium. This block abolishes skin sensation on the medial and dorsal aspects of the antebrachium.

and caudal aspect of the accessory cephalic and cephalic veins, about halfway between the carpus and elbow (see [Figure 10-13](#)).²¹ Alternatively, this nerve can be blocked before it branches, as it courses across the lacertus fibrosus. At this location, the nerve is easily palpable in most horses. A third method to completely abolish skin sensation is using a circumferential subcutaneous ring block, a technique that can effectively block all four cutaneous antebrachial nerves but requires a large volume of local anesthetic solution.

INTRAARTICULAR ANALGESIA IN THE FORELIMB

Distal Interphalangeal Joint

The assumption is that analgesia of the DIP joint is specific for intraarticular pain, but clinical experience and the results of recent clinical and anatomical investigations have convinced us otherwise (see [Figure 10-1](#)). Of great clinical interest is the comparative accuracy of analgesia of the DIP joint and navicular (podotrochlear) bursa in the diagnosis of navicular syndrome. Overall, analgesia of the navicular bursa is likely the most specific technique to diagnose navicular syndrome. However, results of two studies suggest that this block may not be as specific as once thought (see the section on analgesia of the [podotrochlear bursa](#)).^{29,30} Analgesia of the DIP joint lacks specificity for intraarticular pain and in fact can eliminate pain associated with many conditions of the foot.²⁹⁻³² For instance, when high-performance liquid chromatography was used to study the effects of 8 mL of mepivacaine injected into the DIP joint, there was local anesthetic solution in the synovium of the navicular bursa in all horses and in the

medullary cavity of the navicular bones in 40% of horses.³³ Similarly, a recent *in vitro* study showed that 15 minutes after injection of 5 mL of 2% mepivacaine into either the navicular bursa or the DIP joint, mepivacaine was detected in the alternate (uninjected) synovial structure in all specimens. In 48% of navicular bursae after DIP joint injection, and in 44% of DIP joints after navicular bursa injection, mepivacaine was present in clinically effective (analgesic) concentrations (>100 to 300 mg/L).³⁴ Anatomical studies showed that nociceptive neurofibers are present in the dorsal and palmar aspects of the collateral sesamoidean ligaments, within the distal sesamoidean impar ligament, and directly innervating the navicular bone, in the periarthicular connective tissues of the DIP joint and proximal intramedullary portions of the distal phalanx.^{35,36} The close anatomical relationship among all of these structures and the palmar digital neurovascular bundles to the DIP joint capsule makes them susceptible to desensitization by local anesthetic solution injected into the DIP joint.³⁶

In a study using a setscrew model to create solar pain at the toe, DIP intraarticular analgesia abolished lameness, leading to the conclusion that pain in distant sites can be abolished using this technique.²² Therefore a positive response to DIP intraarticular analgesia could mean lameness is caused by an articular problem, navicular syndrome, or, for that matter, solar pain. Close juxtaposition between the palmar synovial extensions of the DIP joint and digital nerves at this level was theorized as the reason that these nerves were blocked, secondary to diffusion of local anesthetic solution from the joint.²² Therefore a protocol to examine a lame horse no longer than 5 minutes after intraarticular analgesia of the DIP joint may theoretically

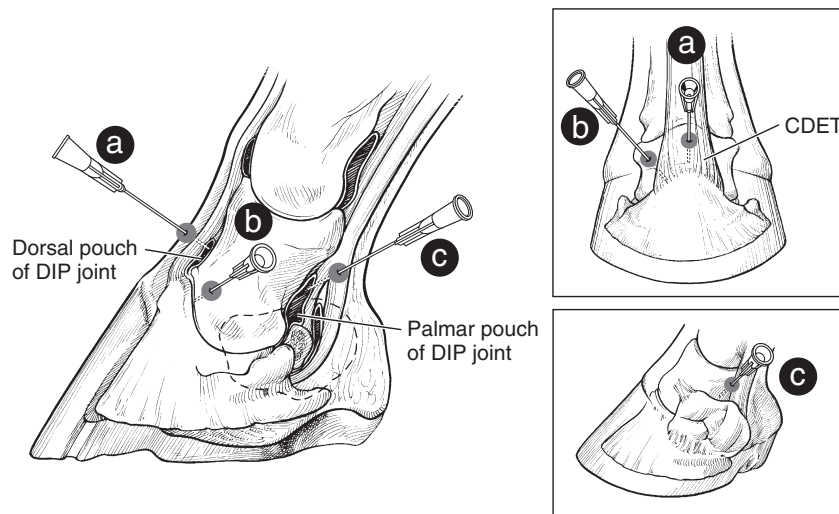

Fig. 10-14 • Lateral view of the foot showing our preferred approach for arthrocentesis of the digital interphalangeal joint using a dorsal midline needle insertion site (a) and directing the needle slightly distally through the common (long) digital extensor tendon. Alternatively, the clinician approaches the digital interphalangeal joint using a site medial or lateral to the extensor tendon (b). The top inset shows the needle positions from the dorsal aspect. The clinician may use a palmar (plantar) approach by positioning the needle between the distal palmar (plantar) border of the middle phalanx and a palpable notch in the proximal border of the cartilage of the foot. The clinician directs the needle (c) in a palmaroproximolateral to dorsodistomedial direction. The lower inset shows the notch into which the needle is inserted. CDET, Common (long) digital extensor tendon; DIP, distal interphalangeal.

minimize diffusion and improve accuracy. However, in one of the Editor's (SJD) experience, pain associated with the navicular bone, navicular bursa, or DDFT has frequently been substantially improved within 5 minutes of injection of the DIP joint. Because diffusion of local anesthetic solution may be hastened by moving the horse, some clinicians prefer the horse to stand until the results of the block are evaluated.⁵

Traditionally, arthrocentesis of the DIP joint has been performed in the dorsal pouch, either medial or lateral to the CDE tendon. A 20-gauge, 2.5- to 4-cm needle is inserted about 1.5 cm proximal to the coronary band, abaxial to the CDE tendon, and directed in a distal and axial direction (Figure 10-14). An easier approach, however, is to insert the needle, angled just slightly distal from horizontal, on the dorsal midline, *through the CDE*. Synovial fluid is consistently obtained using this approach. One of the Editors (SJD) angles the needle more vertically, inserting it in the palpable dip in the distal dorsal aspect of the pastern. For the dorsal aspect of the DIP joint to be opened up, the limb should be positioned slightly ahead of the contralateral limb, and the horse should be in a standing position. Five to 10 mL of local anesthetic solution have been used traditionally, but a maximum of 6 mL may prevent leakage from the joint. Use of a lower volume of local anesthetic solution *may* also improve the specificity of the block, as was shown in a similar study using setscrews to create solar pain. Decreasing the volume of local anesthetic solution in the DIP joint from 10 mL to 6 mL resulted in a significant reduction in lameness caused by pain at the dorsal margin of the sole, but *not* at the angles of the sole.³⁷ The horse is examined after 5 minutes.

Alternatively, a lateral approach to the DIP joint can be used (see Figure 10-14). Landmarks include the distal palmar border of the middle phalanx dorsally and the

palpable notch in the proximal border of the lateral cartilage of the foot distally. A 4-cm needle is inserted laterally and directed in a dorsodistomedial direction. This technique, however, is less reliable than the dorsal approach, because contrast material entered exclusively the DIP joint in only 13 of 20 specimens and in 7 specimens inadvertently entered the navicular bursa or DFTS.³⁸

Proximal Interphalangeal Joint

Arthrocentesis of the proximal interphalangeal joint is most commonly performed in the dorsal pouch. Effusion is rarely present even in horses with severe lameness, a situation that makes arthrocentesis challenging. The injection site is just lateral (or medial) to the CDE tendon at a level of or just distal to the distal, palmar process of the proximal phalanx, located and easily palpable on the distopalmar aspect of this bone. With the horse in the standing position, a 20-gauge, 2.5-cm needle is directed slightly distally and medially (using the dorsolateral approach) and inserted until articular cartilage is encountered (Figure 10-15). Although a desirable sign, synovial fluid appearing in the hub of the needle is an unusual occurrence. Local anesthetic solution, 5 to 10 mL, is injected, and the horse is examined after 5 minutes.

An alternative approach that one author (MWR) finds much easier to perform is approaching the proximal palmar pouch of the proximal interphalangeal joint from the lateral aspect. The injection location is a V-shaped notch, located dorsal to the neurovascular bundle and between the distal palmar process of the proximal phalanx and the insertion of the lateral branch of the SDFT (see Figure 10-15). The limb is held off the ground with the digit in flexion, and a 2.5- or 4-cm needle is directed distomedially (and slightly dorsally) at an angle of about 30 degrees from the transverse plane until fluid is collected (generally at a

Fig. 10-15 • A, Dorsolateral view of the digit showing the site for arthrocentesis of the dorsal pouch of the proximal interphalangeal joint. The clinician inserts the needle just abaxial to the common digital extensor tendon at a site level with the palpable distal palmar (plantar) process of the proximal phalanx. **B**, Flexed lateral view of the digit indicating the site for arthrocentesis of the palmar (plantar) aspect of the proximal interphalangeal joint. The clinician inserts the needle into the V-shaped notch formed by the distal palmar (plantar) aspect of the proximal phalanx dorsally, the bony eminence associated with the attachment of the lateral collateral ligament to the distal aspect of the proximal phalanx and proximal aspect of the middle phalanx distally, and the insertion of the lateral branch of the superficial digital flexor tendon palmarodistally (plantarodistally). The clinician directs the needle distomedially (in a slightly dorsal direction) at an angle of about 30 degrees from the transverse plane until fluid appears. CDET, Common (long) digital extensor tendon; PIP, proximal interphalangeal.

depth of 2 to 3 cm).³⁹ Advantages of this compared with the dorsal approach include less needle manipulation, a larger injection volume, and more frequent recovery of synovial fluid. The technique is difficult to perform with the limb in an extended weight-bearing position, because the palmar or plantar aspect of the proximal interphalangeal joint is compressed. Furthermore, diffusion of local anesthetic solution into palmar soft tissue structures can confound interpretation of results.⁵

Metacarpophalangeal Joint

Four sites commonly used for arthrocentesis of the metacarpophalangeal joint include the dorsal, proximopalmar, and distopalmar sites and the approach through the collateral ligament of the proximal sesamoid bone. The two most commonly used, the dorsal and proximopalmar sites, have potential disadvantages compared with the less commonly used sites. The dorsal pouch can be prominent in horses with effusion, but inadvertently stabbing articular cartilage repeatedly is common when this approach is used. The proximopalmar pouch or recess is large and easily identified, but prominent synovial villi often occlude the needle end, complicating retrieval of synovial fluid, even in horses with severe effusion. Hemorrhage associated with large intracapsular vessels is also a common complication with the proximopalmar approach. The palmar pouch is located dorsal to the suspensory branch, palmar to the McIII, proximal to the collateral sesamoidean ligament, and distal to the bell of the splint bone (Figure 10-16).

Fig. 10-16 • Positive contrast arthrogram of the metacarpophalangeal joint showing the extensive nature of the palmar pouch that extends proximally to the level of the distal end of the splint bones. The distopalmar outpouchings are reliable sites for retrieval of synovial fluid and injection.

Fig. 10-17 • A, Palmarolateral (plantarolateral) view of the left metacarpophalangeal (metatarsophalangeal) joint and digit showing the sites for arthrocentesis of the proximal palmar (plantar) pouch (a), the dorsal pouch (b), the distal palmar (plantar) pouch (c), and the palmar (plantar) pouch through the collateral ligament of the proximal sesamoid bone (d). **B,** Our preferred site for metacarpophalangeal (metatarsophalangeal) joint arthrocentesis, the distal palmar (plantar) approach, using a site just proximal to the lateral palmar (plantar) process of the proximal phalanx, is easily located in the standing or flexed position. **C,** Palmarolateral (plantarolateral) view of the digit indicating sites for synoviocentesis of the proximal (a) and distal (b) aspects of the digital flexor tendon sheath. Proximally, the clinician inserts the needle proximal to the palmar (plantar) annular ligament, and distally inserts the needle on the palmar (plantar) midline into an outpouching of the digital flexor tendon sheath between the proximal and distal digital annular ligaments.

Arthrocentesis using the proximopalmar approach can be performed with the limb in the standing position or being held. An 18- to 22-gauge, 2.5- to 4-cm needle is inserted in the center of the pouch and directed slightly distally in the frontal plane until synovial fluid is recovered (Figure 10-17). It may be necessary to aspirate synovial fluid if the joint capsule is not distended.

Dorsally, arthrocentesis is performed medial or lateral to the CDE tendon (see Figure 10-17). With the limb in a standing or flexed position, the clinician can insert a needle in the distal aspect of the palmar pouch, through

the collateral sesamoid ligament, a less common but effective approach for arthrocentesis of the metacarpophalangeal joint. The technique is more easily performed with the joint held in flexion. This approach for arthrocentesis was shown to be associated with less subcutaneous and synovial inflammation than was the proximopalmar approach⁴⁰ and is the technique routinely used by one of the Editors (SJD).

Under most circumstances we prefer to perform arthrocentesis of the metacarpophalangeal joint using the distopalmar approach. The injection site is in a small but

reliable recess bounded by a triad of structures. Just proximal to the readily palpable proximal, palmar process of the proximal phalanx is a distinct depression. The dorsal aspect of the proximal sesamoid bone and the palmar condyle of the McIII complete the triad but are not readily palpable. The injection site is *dorsal* to the neurovascular bundle. Synovial fluid is consistently retrieved because the injection site is in the most distal aspect of the joint, and hemorrhage is rare. A large volume of fluid can be collected, if desired, because this area is devoid of the large synovial villi that complicate the proximopalmar approach. With the horse in a standing position, a 20-gauge, 2.5-cm needle is inserted, parallel to the ground, in a dorsomedial direction until fluid is obtained (see [Figure 10-17](#)). The needle can be advanced to the hub, but the joint is quite superficial in this location. This technique can also readily be performed with the limb being held in a flexed position.

Ten mL of local anesthetic solution are injected, and the horse is reexamined in 5 to 10 minutes. In horses with subchondral bone pain, additional time may be necessary, but perineural analgesia may be necessary to abolish lameness in these horses. Diffusion of local anesthetic solution may account for partial or complete improvement in lameness in horses with suspensory branch desmitis, sesamoiditis, or injury of the straight, cruciate, or oblique sesamoidean ligaments. Therefore timely evaluation of horses after metacarpophalangeal analgesia is necessary.

Carpal Joints

Arthrocentesis of the middle carpal or antebrachiocarpal joints is one of the easiest and most straightforward of all joint injection techniques. With the carpus in flexion, injection sites are easily identified, and large portals exist through which to access the joints. Portals can be found either medial to the extensor carpi radialis (ECR) tendon or between the ECR and the CDE tendons ([Figure 10-18](#)). The middle carpal and carpometacarpal joints always communicate, but a communication between the middle carpal and antebrachiocarpal joints rarely exists. A communication between the middle carpal joint and carpal sheath only rarely is encountered clinically, but was not seen in a study using cadaver limbs. Analgesia of the middle carpal and antebrachiocarpal joints should be performed separately to differentiate lameness between these independent cavities. However, even though gross anatomic communications rarely exist between these joints, a recent *in vitro* study revealed the potential for diffusion of mepivacaine from one joint to the other by 15 minutes after either was injected with 10 mL of 2% mepivacaine. In only a small percentage were the concentrations of mepivacaine in each joint at levels thought to produce clinical analgesia. How this translates to the live horse also remains unknown. Nonetheless, the clinician is reminded of the importance of prompt reevaluation to minimize misinterpretation of the results, but also to keep an open mind if results of diagnostic imaging do not seem compatible with the results

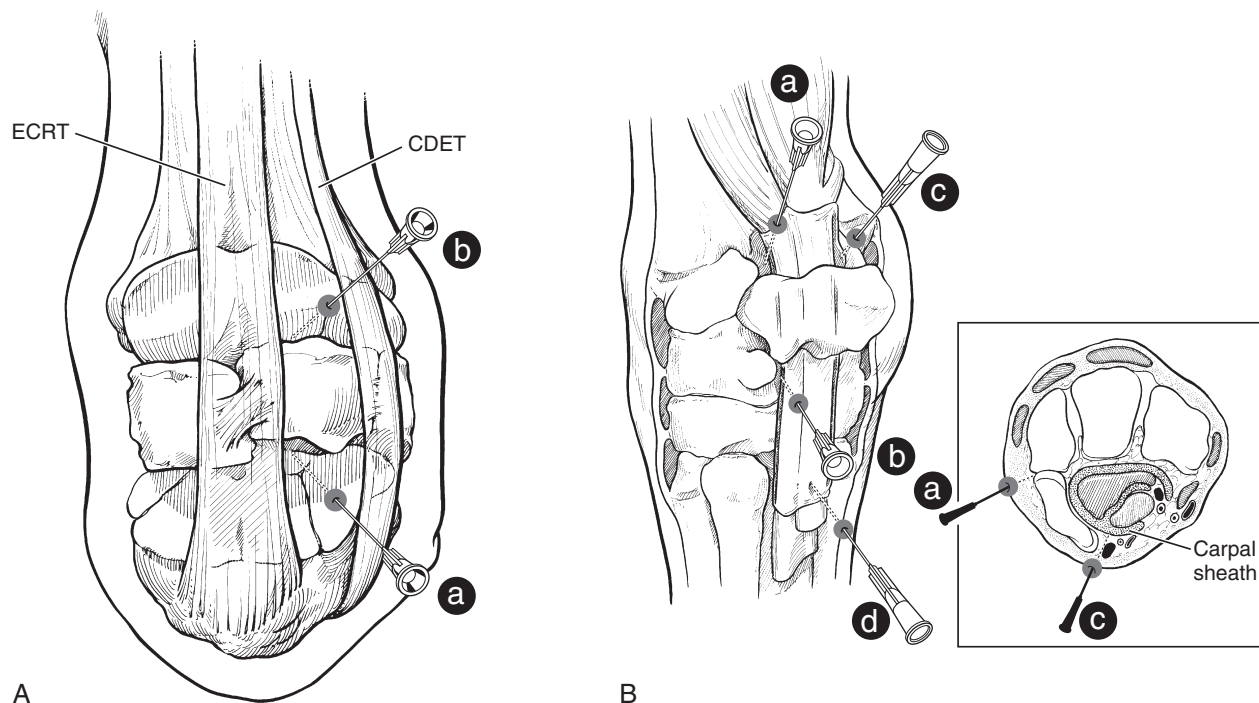

Fig. 10-18 • A, Dorsal view of the left carpus in a flexed position showing the sites for arthrocentesis of the middle carpal (a) and antebrachiocarpal (b) joints. Needles are usually positioned between the extensor carpi radialis and common digital extensor tendons (as shown), but sites for injection of both joint cavities located medial to the extensor carpi radialis tendon can be used. **B,** Lateral view of the left carpus demonstrating sites for arthrocentesis of the proximal palmar pouch of the antebrachiocarpal joint (a), the palmarolateral pouch of the middle carpal joint (b), and the proximal (c) and distal (d) pouches of the distended carpal sheath. The inset shows the relative needle positions to enter the palmar pouch of the antebrachiocarpal joint and the carpal sheath. CDET, Common (long) digital extensor tendon; ECRT, extensor carpi radialis tendon.

of diagnostic analgesia.³⁴ Distopalmar outpouchings of the carpometacarpal joint complicate interpretation of analgesic techniques, because these extend a mean distance of 2.5 cm distal to the carpometacarpal articulation and are closely associated with the suspensory ligament origin and the palmar metacarpal nerves (see [Figures 10-8 to 10-10](#)).⁴¹ Careful differential analgesic techniques and comprehensive imaging are necessary for accurate diagnosis of lameness in the carpal and proximal metacarpal regions.

Typically, a 20-gauge, 2.5-cm needle is used to inject 5 to 10 mL of local anesthetic solution into the middle carpal and antebrachicarpal joints. If the skin can be prepared aseptically on the dorsal aspect, the injections are most commonly performed with the joint in 90 to 120 degrees of flexion. The clinician can maintain flexion, but having an assistant hold the limb securely is easier.

If the dorsal aspect of the carpus cannot be prepared aseptically, as occurs commonly in racehorses with chemically induced dermatitis (scurf), or if an additional site is needed for thorough lavage, the palmarolateral pouches of the middle carpal and antebrachicarpal joints can be used. The palmar pouch of the antebrachicarpal joint is bounded by the lateral digital extensor tendon dorsally and the ulnaris lateralis tendon palmarly. In horses with substantial effusion, this pouch is easily identified but must be differentiated from the lateral outpouching of the carpal sheath. Arthrocentesis can be performed either proximally or distally in the palmar pouch (see [Figure 10-18](#)). The distal injection site is located in a shallow recess between the distal lateral radius (ulna) and the ulnar carpal bone, just distal to the V-shaped convergence of the lateral digital extensor and ulnaris lateralis tendons. With the horse in a standing position, a 20-gauge, 2.5-cm needle is inserted perpendicular to the skin and advanced until synovial fluid is recovered.

The palmar pouch of the middle carpal joint is similarly accessed in a shallow depression between the ulnar and fourth carpal bones, located 2 to 2.5 cm distal to the recess palpated to access the antebrachicarpal joint in the palmar aspect (see [Figure 10-18](#)). The shallow depression in the middle carpal joint is difficult to palpate, but in horses with severe effusion an outpouching of the joint is palpable. This approach is undertaken with the limb in a standing position, decreases the potential for iatrogenic cartilage injury, and is less dangerous to the clinician because the procedure is performed on the side rather than in front of the limb.⁴² The injection is more difficult and less commonly used, however.

Cubital (Elbow) Joint

Two sites are used for arthrocentesis of the elbow joint. The cranial pouch is accessed at the level of the radiohumeral articulation, just cranial to the lateral collateral ligament. The lateral collateral ligament courses between the palpable lateral tuberosity of the radius and the lateral epicondyle of the humerus ([Figure 10-19](#)). An 18- or 20-gauge, 6- to 9-cm needle is directed medially and slightly caudally to a depth of 5 to 6 cm, beginning in the adult horse, about 3.5 cm proximal to the lateral tuberosity of the radius and 2.5 cm cranial to the lateral collateral ligament.¹⁹ To account for differences in horse size, the injection site is generally located two thirds of the distance between the humeral epicondyle and the lateral tuberosity of the radius.

This block may be more easily performed closer to the lateral collateral ligament, and at this site the joint is penetrated in a more superficial location.⁵ Before injection, every effort should be made to verify that the needle is actually in the joint. Periarticular deposition of local anesthetic solution in this location can induce temporary radial nerve dysfunction, and horses may lose the ability to extend the carpus and digit.⁴³ Twenty to 25 mL of local anesthetic solution are used. An older approach relied on injection of local anesthetic solution into the ulnaris lateralis bursa, once universally thought to communicate with the elbow joint. The frequency of communication between the elbow joint and ulnaris lateralis bursa was determined to be 37.5%, and therefore this approach is no longer recommended.⁴⁴

We prefer to perform arthrocentesis in the proximolateral aspect of the caudal pouch in the palpable depression cranial to the olecranon process and caudal to the lateral epicondyle of the humerus. In most horses the site of needle penetration is 3 to 3.5 cm caudal to the lateral epicondyle (see [Figure 10-19](#)). In small horses and ponies, an 18- or 20-gauge, 4-cm needle is sufficient, but in large horses a 9-cm spinal needle is often necessary because the injection site is at the distal extent of the lateral head of the triceps muscle. The needle is advanced for 5 to 7 cm in a distal, slightly cranial, and medial direction until synovial fluid is recovered. However, this technique is often less well tolerated by difficult horses compared with the cranial pouch technique.

Elimination of skin sensitivity at the site of needle insertion by depositing a small volume of local anesthetic solution may facilitate elbow arthrocentesis, because numerous attempts may be necessary. Synovial fluid is consistently retrievable from the joint with proper needle positioning.

Scapulohumeral (Shoulder) Joint

The shoulder joint is frequently blamed for lameness in many horses but, based on the results of diagnostic analgesia, is an uncommon source of pain. Arthrocentesis of this joint is most commonly performed at a site between the cranial and caudal prominences of the greater tubercle of the humerus, just cranial to the infraspinatus tendon. This tendon is easily palpated in most horses and serves as the primary landmark. Firm, careful palpation between the cranial and caudal prominences reveals a depression or notch, which is the point of needle insertion (see [Figure 10-19](#)). Identification of landmarks is easier in horses with muscle atrophy resulting from chronic lameness.

In most horses an 18- to 20-gauge, 9-cm spinal needle is preferred, although using the entire length is not necessary. Elimination of skin sensitivity is usually not necessary. The needle is inserted in a caudomedial direction (about 45 degrees from lateral), and directed slightly distally. Attaching a syringe to aspirate synovial fluid is sometimes necessary, because in joints with minimal effusion, confirming intraarticular position of the needle may be difficult. A total of 25 to 30 mL of local anesthetic solution is used, and the horse is assessed 10 and 30 minutes after injection, because severe pain associated with osteochondrosis may resolve slowly. Analgesia of the suprascapular nerve and subsequent supraspinatus and infraspinatus muscle paralysis were reported after attempts at intraarticular shoulder

Fig. 10-19 • Lateral view of the left elbow and shoulder regions. For arthrocentesis of the cranial pouch of the elbow (cubital) joint, the clinician directs the needle (a) medially and slightly caudally to a depth of about 5 to 6 cm at a point about 3.5 cm proximal to the lateral tuberosity of the radius and 2.5 cm cranial to the lateral collateral ligament. Arthrocentesis of the proximal, caudal pouch (b) is performed at a site in the palpable depression between the cranial aspect of the olecranon and the caudal aspect of the lateral epicondyle of the humerus. One injection site is for the rarely performed technique of synoviocentesis of the olecranon bursa (c). Proximally is the site for arthrocentesis of the scapulohumeral joint (d). A needle is inserted cranial to the infraspinatus tendon in the notch between the cranial and caudal eminences of the greater tubercle of the humerus and advanced in a caudomedial direction, roughly parallel to the ground and about 45 degrees to the long axis of the body (*inset*). For the bicipital bursa (e), the clinician inserts the needle at a point about 4 cm proximal to the palpable distal aspect of the deltoid tuberosity of the humerus (or alternatively, a point about 3 to 4 cm distal and 6 to 7 cm caudal to the palpable aspect of the cranial process of the greater tubercle) and directs it proximally and medially, and in some patients slightly cranially.

analgesia.⁴³ This complication is uncommon, in our experience, and may result from proximal periarticular injection of local anesthetic solution. An alternative explanation is anesthetic solution diffusion to nerves of the brachial plexus.⁵ Trauma from numerous needle insertions or injection of large volumes of local anesthetic solution (>30 mL) may increase the likelihood of this complication. In fact, some have recommended using only 8 to 10 mL, but false-negative results from the block would likely occur.⁴³ Our opinion is that the most likely cause of this rare complication is malposition of the needle or iatrogenic trauma. Rarely, a communication between the bicipital bursa and the shoulder joint occurs.⁴⁵ Thinking a horse has shoulder joint pain is possible then, but in reality the diagnosis is bicipital bursitis or tendonitis. Rather than a communication between the structures, the most likely explanation is inadvertent penetration of the bicipital bursa from a misdirected needle.

ANALGESIA OF FORELIMB BURSAE AND TENDON SHEATHS

In most instances, analgesia of bursae and tendon sheaths is achieved using perineural techniques, but in some horses, selective intrasynovial analgesia is indicated. Pain sensation from bursae and sheaths is likely complex, and lameness after intrabursal or intrathecal (within a sheath) analgesia may improve but not completely resolve. In fact, horses with severe lameness resulting from bursitis or tenosynovitis often have other associated soft tissue damage, a fact that explains partial improvement after intrasynovial analgesia. Extra time is usually given, after blocking, to reassess the horse's clinical signs.

Podotrochlear (Navicular) Bursa

As was noted previously (see DIP joint analgesia), analgesia of the navicular bursa has generally been regarded as the

most specific block for diagnosis of navicular syndrome. Although likely still true, the results of at least two studies suggest there is potential for misinterpretation of the results of analgesia of the navicular bursa, and we question the specificity of the block. With a setscrew model used to induce solar pain, it was shown that injection of 3.5 mL of local anesthetic solution into the navicular bursa significantly reduced lameness scores in horses with pain at the dorsal aspect of the sole (but not the palmar aspect) within 15 minutes.²⁹ In a complementary study using endotoxin-induced synovitis of the DIP joint, injection of the navicular bursa with 3.5 mL of local anesthetic solution had no effect on lameness score at 10 minutes, but lameness was substantially decreased 20 minutes after injection (though not to a statistically significant degree [$P = .07$]).³⁰ Nonetheless, the clinical experience of one of the Editors (SJD) indicates that intrathecal analgesia of the navicular bursa is reasonably reliable in improving pain associated with lesions of the navicular bone, navicular bursa, and distal aspect of the DDFT, whereas pain associated with the collateral ligaments of the DIP joint is not affected.

A palmar midline approach is most commonly used for analgesia of the navicular bursa. Because needle position is difficult to assess and fluid recovery varies, radiographs should be used to confirm proper needle position. Alternatively radiodense contrast medium can be injected together with the local anesthetic solution, and a lateromedial radiographic image can then be obtained to determine that the injection was into the navicular bursa. Positioning the foot on a wooden block can minimize the problems of manipulation at the bulbs of the heel and helps to maintain aseptic technique. Subcutaneous deposition of a small volume (1 to 2 mL) of local anesthetic solution can improve horse compliance during this procedure. An 18- to 20-gauge, 9-cm

spinal needle is inserted on the palmar midline, just proximal to the hairline, and directed parallel to the sole until the needle contacts bone (Figure 10-20).^{25,27,46} Others describe a similar approach, although they direct the needle parallel to the coronary band.^{21,47,48} Because redirection of the needle proximally or distally often is necessary, these approaches differ little. Success depends most on personal experience, but radiographs can be critical in confirming successful entry into the navicular bursa. The direction in which the needle is inserted is often dictated by the shape of the horse's foot and the projected position of the navicular bone.⁵ Plotting and marking the navicular position on the hoof wall can be helpful in determining needle direction and depth of insertion. The navicular position is located at a site 1 cm distal to and halfway between the dorsal and palmar aspects of the coronary band.^{48,49} However, with experience and after identifying the navicular position, the procedure can be done blindly. In most horses the flexor surface of the navicular bone will be contacted at a depth of 4 to 5 cm. The needle is likely improperly positioned if resistance is encountered at a depth of less than 3 to 4 cm or if the needle can be advanced more than 6 to 7 cm. Spontaneous retrieval of synovial fluid is rare and usually indicates that the needle is in the DIP joint capsule or the DFTS. To avoid penetrating these structures, the needle should be placed in the middle of the flexor surface of the navicular bone.⁵ Three to 5 mL of local anesthetic solution are used. If navicular syndrome is suspected, some clinicians combine injection of local anesthetic solution with a corticosteroid. Alternatively, navicular bursography⁵⁰ can be performed in combination with diagnostic analgesia by adding 1 to 2 mL of sterile, iodinated contrast material (see Chapter 30). Because in the standing horse the navicular bursa is under compression by the DDFT, suspending the

Fig. 10-20 • A, Lateral view showing two techniques for synoviocentesis of the navicular bursa of the foot. In the palmar (plantar) approach (*a*) the needle is placed just proximal to the hairline between the bulbs of the heel and inserted to the navicular bursa using the navicular position as a guide. The navicular position (*arrow*) is located by determining the point on the outside of the hoof wall that is 50% of the distance from the dorsal to the palmar (plantar) extent of the coronary band and 1 cm below (*inset*). An approach slightly more proximal (*b*) requires placing the needle in the depression between the heel bulbs and advancing the needle in a dorsodistal direction, about 30 degrees from horizontal toward the navicular position. **B,** Palmarolateral (plantarolateral) view of the digit showing the lateral approach for synoviocentesis of the navicular bursa. The needle is inserted just proximal to the cartilage of the foot between the digital neurovascular bundle and the digital flexor tendon sheath and directed axially, distally, and slightly dorsally.

foot or placing the toe in a “navicular block” as if for radiography, with the foot in partial flexion during actual injection, are useful. Without using radiographs, being confident of accurate needle placement is difficult.

A proximal, palmar injection technique has been described. A needle is inserted into the deepest part of the hollow between the heel bulbs and advanced dorsodistally, about 30 degrees from horizontal, until contact with the bone is made.^{45,51} A lateral (or medial) approach is also described. A needle is inserted just proximal to the cartilage of the foot, between the neurovascular bundle and the DFTS and directed axially, distally, and slightly dorsally until contact with bone is made (see Figure 10-20).^{46,48,52} These five techniques were compared in an *in vitro* study. The most reliable technique was determined to be the distal palmar approach, with the needle being directed to the navicular position and the limb in a non-weight-bearing position.⁵³

Digital Flexor Tendon Sheath

Two sites for intrasynovial injection of the DFTS are just proximal to the palmar (plantar) annular ligament (PAL) or in the palmar aspect of the pastern region in an out-pouching of the sheath located between the proximal and distal digital annular ligaments (see Figure 10-17). Effusion facilitates identification of these sites, and rarely would an intrathecal injection be contemplated without the presence of effusion. Proximal to the PAL, villous hypertrophy of synovial membrane can complicate the procedure, because even with severe distention of the sheath, synovial fluid may be difficult to retrieve. For this reason we favor the palmar pastern approach. In some horses the sheath appears to be compartmentalized and distended proximal to the PAL but not below, and therefore injections are easier to perform proximally. A 20-gauge, 2.5-cm needle and 10 to 15 mL of local anesthetic solution are used (see also Figure 124-1). In contrast to intrasynovial analgesia in other locations in the digit, analgesia of the DFTS appears to be quite specific for lameness associated with pain arising from structures contained within it.⁵⁴ In other words, unless local anesthetic solution is inadvertently injected outside of the DFTS or leaks from it after injection, analgesia of nearby digital nerves and structures appears unusual. However, local diffusion may result in alleviation of pain from the oblique or straight sesamoidean ligaments.⁵⁵

Alternatives to these approaches for intrasynovial injection of the DFTS are described. The procedure can be performed at a site just distal to the PSBs, between the distal aspect of the PAL and the proximal aspect of the proximal digital annular ligament (see Figure 10-17). A palmar axial sesamoidean approach has been described. With the metacarpophalangeal joint held in flexion (225-degree angle between the McIII and the proximal phalanx), a 20-gauge, 2.5-cm needle is inserted at an angle of 45 degrees, 3 mm axial to the palmar border of the PSB (midbody) and just palmar to the neurovascular bundle. Putative advantages included more reliable access to the DFTS when effusion is absent and reduced time required for successful entry.⁵⁶

Carpal Sheath

The carpal sheath (carpal flexor sheath) envelops the SDFT and DDFT in the carpal canal. Distention of the carpal sheath is most easily recognized laterally, just proximal to

the accessory carpal bone, between the lateral digital extensor and ulnaris lateralis tendons (see Figure 10-18). Effusion of the carpal sheath must be differentiated from that of the antebrachiocondylar joint. Concurrent distention of the dorsal aspect of the antebrachiocondylar joint or distention of the distal aspect of the carpal sheath (lateral or medial, distal to the flexor retinaculum on the palmar aspect of the metacarpal region) is a sign that is helpful in determining this. Ultrasonographic evaluation or positive contrast radiography can be useful adjunct diagnostic techniques. Synoviocentesis can be performed in either the proximal or the distal aspect of the sheath, using a 20-gauge, 2.5-cm needle and 10 to 15 mL of local anesthetic solution.

Olecranon Bursa

This technique is mentioned to be complete, but we have never found an indication to perform analgesia of this bursa (see Figure 10-19). If distended, this bursa could be entered using the same techniques described for other bursae. Rarely, local analgesia over implants used to repair olecranon process fractures is necessary to investigate whether implant removal is indicated.

Bicipital Bursa

Bicipital bursitis and shoulder lameness are frequently diagnosed but in reality are uncommon causes of lameness, if the clinician religiously adheres to the principles of diagnostic analgesia. However, bicipital bursitis and tendonitis and proximal humeral osteitis, fractures, or osseous cystlike lesions can cause lameness and are diagnosed using analgesia of the bicipital bursa. The bicipital bursa is located between the greater and lesser tubercles of the humerus and the overlying tendon of origin of the biceps brachii muscle. Synoviocentesis of the bicipital bursa is routinely performed from a lateral approach, but if severe effusion exists, the bursa can be accessed medially. The injection site is located just cranial to the humerus, 4 cm proximal to the distal aspect of the deltoid tuberosity.⁴⁶ Alternatively, the site can be located by finding a point 3 to 4 cm distal and 6 to 7 cm caudal to the cranial process of the greater tubercle (see Figure 10-19).¹⁹ Subcutaneous infiltration of local anesthetic solution at the site can be used but is rarely needed. An 18-gauge, 9-cm needle is directed in a proximal, medial, and slightly cranial direction and can be “walked off” (shaft of the needle in contact with the bone) the cranial cortex of the humerus. A change in resistance is felt, and synovial fluid may be seen in the needle hub or can be aspirated. Ten to 20 mL of local anesthetic solution are used. If injection is difficult, synovial fluid cannot be retrieved, and retrieving local anesthetic solution already injected is not possible, the bursa likely has not been entered. A recent study showed a high failure rate of injection with either technique.⁵⁷ Moreover, false-negative results also occur, despite retrieval of synovial fluid, in association with severe lesions of the tendon of biceps brachii or in the presence of dystrophic mineralization or ossification.⁵⁸ An alternative is to use an ultrasound-guided technique, which may be more accurate.

PERINEURAL ANALGESIA IN THE HINDLIMB

Perineural analgesia in the distal aspect of the hindlimb is similar to that described for the forelimb. Minor differences

in innervation and anatomy must be taken into consideration, however. Technical differences in whether, or how, the limb is held and other intangible differences exist. Most clinicians are not as familiar, or frankly as comfortable, with performing hindlimb analgesic techniques, and this is particularly true with perineural analgesia. It takes a dedicated lameness detective to be enthusiastic about hindlimb analgesia, particularly in fractious or highly strung horses. Obviously, safety for the veterinarian and assistants is paramount, and physical and chemical restraint become important. Performing intraarticular analgesia is far easier, but the clinician must keep in mind that perineural techniques are much more effective in abolishing subchondral bone pain. Therefore false-negative results will likely be obtained if one is limited to only intraarticular procedures. We generally recommend that most perineural techniques distal to the tarsus be performed with the limb held off the ground by an experienced assistant, but personal preference can of course prevail. In some instances, such as when plantar digital analgesia is performed, the anatomy is much easier to identify when the limb is bearing weight. One of the Editors (SJD) routinely performs the majority of hindlimb local analgesic techniques with the limb bearing weight, and with the horse restrained in wooden stocks. The hindlimb can be positioned behind or just in front of the back wooden post; the clinician is then protected by the post if the horse kicks.

To limit the number of hindlimb injections in horses that lack clinical signs referable to the digit, starting with the low plantar block (low 4 point or 6 point block) may be reasonable, in lieu of performing sequential blocks starting with plantar digital analgesia. Of course, performing blocks distal to this site at another time may be necessary if baseline lameness is discovered using this approach. The clinician should take care when testing the efficacy of hindlimb blocks, and using a pole or similar device may be safer than using forceps.⁵ Complete abolition of skin sensation in the hindlimb is less likely than in the forelimb because the distribution of cutaneous innervation varies.

Plantar Digital Analgesia

The technique for plantar digital analgesia is essentially the same as in the forelimb (see [Figure 10-5](#)). The prevalence of lameness abolished by plantar digital analgesia in the hindlimb is considerably lower than palmar digital analgesia in the forelimb but is not zero, and therefore this block should still represent a good starting point for a horse with undiagnosed hindlimb lameness. Because of the reciprocal apparatus, the digit is constantly flexed when the limb is held off the ground, and this block can be slightly more difficult to perform in this position. However, just as in the forelimb, results can be misleading with abolition of pastern or fetlock region pain.

Dorsal Ring Block of the Pastern

The section on the dorsal ring block of the pastern in the forelimb describes this technique (see [Figure 10-5](#)). This block requires several needle insertions and can be difficult to perform if the limb is held off the ground, because the dorsal aspect of the pastern is constantly flexed, making subcutaneous injection difficult.

Basisesamoid and Abaxial Sesamoid Blocks

Basisesamoid and abaxial sesamoid blocks present no essential differences between the forelimbs and hindlimbs (see [Figure 10-5](#)). Our philosophical points about the basisesamoid block (see forelimb) hold true in the hindlimb as well. The abaxial sesamoid block is avoided, if possible, in racehorses, because the high prevalence of lameness involving the metatarsophalangeal joint may lead to inadvertent misdiagnosis (a positive response to the block will be interpreted as lameness in the foot, when in reality lameness involves the metatarsophalangeal joint).

Low Plantar Block

Analgesia of the metatarsophalangeal joint region is achieved using the low plantar block, a procedure similar to the low palmar block (see [Figure 10-7](#)). This block is one of the most overlooked but most useful of all perineural techniques. It is essential to block the medial and lateral and plantar and the medial and lateral plantar metatarsal, and in some horses the dorsal metatarsal nerves. For routine diagnostic analgesia we do not block the dorsal metatarsal nerves, but for therapeutic analgesia they should be blocked. Anecdotal information suggests that some practitioners may not include the plantar metatarsal nerves when performing this block. The plantar metatarsal nerves supply innervation to the subchondral bone of the distal aspect of the third metatarsal bone (MtIII), and to provide analgesia to this important area, these nerves need to be blocked. In fact, a modification of this technique can be used in horses suspected of having subchondral, maladaptive, or nonadaptive remodeling of the MtIII, a common diagnosis in Standardbred and Thoroughbred racehorses (see Chapters 106 to 109). A positive response to an independent block of the lateral plantar metatarsal nerve can help establish this syndrome as the cause of lameness. Other causes of pain arising from the lateral aspect of the metatarsophalangeal joint, including fractures of the lateral condyle of the MtIII or of the PSBs, can be abolished using this modified technique.

The only difference between the low palmar and low plantar blocks involves the dorsal aspect of the limb (see [Figure 10-7](#)). Skin sensation laterally and medially is retained after this block, unless a circumferential, subcutaneous ring block is used. In the forelimb, it is necessary to use subcutaneous infiltration only to the dorsal midline. Alternatively, the dorsal metatarsal nerves can be blocked individually.

High Plantar Nerve Block

The high plantar or subtarsal block is one of the most important but often overlooked perineural analgesic procedures in the horse. This block is used to diagnose suspensory desmitis, arguably one of the most important lameness conditions in the hindlimb. However, suspensory desmitis can be a catchall diagnosis in some horses with occult hindlimb lameness, and the high plantar block must be done to confirm the authentic location of pain. The high plantar block should be done after completion of lower limb blocks such as low plantar analgesia to rule out other common sources of pain. Practitioners should be wary of a recent trend to complete only a subtarsal block to diagnose, erroneously in some horses, proximal suspensory desmitis, when sequential distal-to-proximal analgesic

Fig. 10-21 • Positive contrast arthrogram of the tarsometatarsal joint showing short, distoplantar outpouchings extending distally toward the origin of the suspensory ligament. Inadvertent penetration of these pouches occurs during subtarsal or high plantar analgesic techniques.

techniques may have revealed an alternative source of pain. The tarsometatarsal joint has distoplantar outpouchings (similar to but less extensive than the distopalmar outpouchings of the carpometacarpal joint) that may complicate tarsometatarsal intraarticular or high plantar analgesic techniques (Figure 10-21). However, this is certainly less of a problem in the hindlimb than in the forelimb. For example, inadvertent penetration of the tarsometatarsal joint occurred in only 5% of limbs in which high plantar analgesia was performed, at a level of 1.5 cm distal to the tarsometatarsal joint. However, contrast material was found in the tarsal sheath in 40% of limbs, adding yet another dimension to this already somewhat difficult blocking technique. False-negative results have been attributed to inadvertent injection into blood or lymphatic vessels.⁵⁹ The clinician should take care in preparing the limb for this procedure and interpreting the results. It is possible, although not likely, that when a high plantar block is performed, local anesthetic solution could be inadvertently placed in the tarsometatarsal joint. A good chance also exists, however, of inducing analgesia of the tarsal sheath. Comprehensive evaluation using numerous imaging modalities is needed when attempting to differentiate causes of lameness in this important area.

The medial and lateral plantar and the medial and lateral plantar metatarsal nerves are blocked, and a circumferential dorsal ring block provides complete analgesia to the metatarsal region. Blocking only the plantar metatarsal nerves can abolish pain associated with the suspensory

Fig. 10-22 • The high plantar block is performed at a level 4 cm distal to the proximal aspect of fourth metatarsal bone and on the medial side 3 cm distal to the proximal aspect of second metatarsal bone. The needles are inserted axial to the respective splint bone and advanced deep to contact the plantar surface of the third metatarsal bone. Local anesthetic solution is deposited in this location to block the lateral (medial) plantar metatarsal nerves and in a more superficial position as the needle is withdrawn blocks the lateral (medial) plantar nerves (*inset*).

ligament. Most clinicians do not include the dorsal ring block, but it is necessary to do so to eliminate lameness resulting from injury of the dorsal cortex of the MtIII or to suture lacerations in this area. This block is performed most commonly and safely with the limb held off the ground. Although uncommon to rare, needle breakage is a complication during high plantar analgesia, and for this reason we prefer to use needles no smaller than 18 to 20 gauge and 4 cm long. At this level on the plantar aspect of the limb, it is impossible to palpate nerves, and unlike with the high palmar block, only one injection site exists for each, on the medial and lateral aspects of the limb. The needle is placed just distal to the tarsometatarsal joint and axial to the fourth metatarsal bone (MtIV) and inserted until contact is made with the MtIII (Figure 10-22). A minimum of 5 mL of local anesthetic solution is deposited at this deep location, and an additional 5 mL are deposited as the needle is withdrawn, leaving a definite bleb in the subcutaneous tissues. Some clinicians prefer lower volumes of local anesthetic solution. Additional local anesthetic solution can be used without risk, and a common modification is flooding the origin of the suspensory ligament with an additional 5 to 10 mL of local anesthetic solution. The procedure is then repeated medially, and the needle is inserted axial to the second metatarsal bone (MtII). To complete the block, a circumferential subcutaneous ring block is performed. The clinician must take care not to lacerate the dorsal metatarsal artery or the saphenous vein during this procedure.

An alternative technique to alleviate pain from the proximal aspect of the suspensory ligament is to block the deep branch of the lateral plantar nerve. This can be performed with the limb bearing weight or lifted, according to personal preference. A 20-gauge needle is inserted perpendicular to the skin just plantar to the MtIV at the

junction where its contour changes from oblique to vertical. The needle is inserted to a depth of approximately 1 cm, and 3 mL of local anesthetic solution are deposited. This block is quick and easy to perform and is generally well tolerated but may not remove pain associated with entheses reaction.⁵ See the following text for a discussion of alternative techniques to block the suspensory origin.

Fibular (Peroneal) and Tibial Nerve Blocks

Analgesia of the distal crus and tarsus or entire distal aspect of the hindlimb is induced using the fibular and tibial nerve blocks. These blocks are used most commonly in horses with distal hock joint pain, in which intraarticular analgesia is difficult or impossible to perform. The fibular and tibial nerve blocks, when completed successfully, are more effective in eliminating pain from the complex hock joints than is intraarticular analgesia. The fibular and tibial nerve blocks also are useful in eliminating pain associated with subchondral trauma of the distal aspect of the tibia and talus, distally located tibial stress fractures, the tarsal sheath, the distal aspect of the common calcaneal tendon, the calcaneal bursa, and the plantar aspect of the hock. The clinician should keep in mind that if the high plantar block has not already been performed, the fibular and tibial nerve blocks eliminate pain associated with proximal suspensory desmitis.

The deep fibular nerve is blocked at a site located laterally, 10 cm proximal to the point of the hock (tuber calcanei), in the groove between the long and lateral digital extensor muscles (Figure 10-23). In this groove the superficial fibular nerve is easily palpated and can be rolled against the fascia of the crus. An 18- to 22-gauge, 4-cm needle is inserted to the hub or until it contacts the lateral tibial cortex, and 10 to 15 mL of local anesthetic solution

are injected, beginning deep and continuing as the needle is withdrawn. The needle can be redirected in a fan-shaped pattern if desired to ensure complete block of the deep branch of the fibular nerve. Seeing blood in the needle hub is common, a reliable sign of accurate needle placement, because the cranial tibial vein and artery are located close to the deep fibular nerve.⁶⁰ Performing the tibial block first is therefore preferable, as is warning the client that blood may appear.⁵ The superficial fibular nerve is blocked as the needle is withdrawn from deep within the injection site. Additional local anesthetic solution (5 to 10 mL) is placed in this subcutaneous location.

The tibial nerve is blocked at a site 10 cm proximal to the tuber calcanei, cranial to the common calcaneal tendon, and caudal to the DDFT (see Figure 10-23). The nerve can be palpated as a firm cordlike structure with the limb in a flexed position. For this reason, performing this block may be easier with the limb not bearing weight. Although the tibial nerve is slightly more superficial medially, the injection can be performed either medially or laterally. A 20-gauge, 2.5-cm needle is inserted laterally, and 15 mL of local anesthetic solution are injected over the nerve. The needle tip should be palpated under the skin, medially, to ensure the proper depth of penetration. Local anesthetic solution can be placed using a fan-shaped injection technique, but the horse will object if the tibial nerve is penetrated. Although deep pain will be abolished if these nerves are successfully blocked, superficial sensation persists on the medial aspect and occasionally in the caudal (plantar) aspect of the limb. To use the fibular and tibial nerve blocks therapeutically, it is necessary to perform a circumferential subcutaneous ring block to completely abolish skin sensation. After the fibular and tibial nerve blocks, paradoxically, preexisting toe drag may persist or increase, despite resolution of weight-bearing lameness.⁵ Some horses stumble or knuckle, indicating loss of extensor muscle function, but this is not common and certainly not a necessary sign to suggest that complete analgesia has been obtained. However, exercising a horse at speed or over fences should be avoided. Because of nerve size and depth, we suggest that additional time be given, as much as 20 to 30 minutes, to evaluate the effect of this block before a final conclusion is reached. Dyson has recognized improvement in horses up to 1 hour after blocking and warns that proceeding with a stifle block too soon leads to false-positive results.⁵ The fibular and tibial nerve blocks are not commonly performed in practice, at least in the United States, and at best may result in only 50% to 80% improvement in lameness score, particularly in those horses with severe distal hock joint pain, although in some horses lameness is abolished completely. Allowing more time for maximal response and taking a realistic approach to the percent improvement expected are warranted when using the fibular and tibial nerve blocks. Intrasynovial analgesic techniques are certainly more specific than are the fibular and tibial nerve blocks, and although the fibular and tibial nerve blocks have limitations, the lameness diagnostician should become familiar and comfortable with this procedure. Proficiency in performing these blocks is a must for accurate diagnosis of hindlimb lameness. Performing the fibular and tibial components can independently improve specificity of the fibular and tibial nerve blocks.

Fig. 10-23 • Lateral view of the left crus and tarsus showing the fibular (peroneal) and tibial nerve block. The deep and superficial fibular nerves are blocked by finding the groove between the long and lateral digital extensor muscles, 10 cm proximal to the tarsus, in which the superficial fibular nerve is palpable. The needle (a) is advanced deep to block the deep branch and withdrawn to a more superficial position to deposit local anesthetic solution subcutaneously to block the superficial branch. The tibial nerve block (b) is performed by palpating the nerve just cranial to the common calcaneal tendon (from either a lateral or a medial approach) in a location about 10 cm proximal to the tuber calcanei.

INTRAARTICULAR ANALGESIA IN THE HINDLIMB

Analgesia of the DIP and proximal interphalangeal joints in the hindlimb is exactly the same as that described for the forelimb. Performing intraarticular analgesia of the metatarsophalangeal joint is the same as that described for the metacarpophalangeal joint. Perineural analgesic techniques should be used whenever possible, because subchondral bone pain is more completely abolished with these techniques, and false-negative results are less likely.

Tarsus

Tarsometatarsal Joint

The most reliable site for arthrocentesis of the tarsometatarsal joint is a lateral approach, just proximal to the MtIV. At this site is a subtle but consistent depression that can reliably be palpated. A 20-gauge, 2.5-cm needle is inserted in a dorsomedial and slightly distal direction (Figure 10-24). The needle can usually be inserted to the hub, but occasionally it hits articular cartilage. Synovial fluid is consistently retrieved, but we find it interesting that even in horses without lameness of the tarsometatarsal joint, the fluid is generally watery, lacking what is thought to be normal viscosity. In most horses, up to 4 mL of local anesthetic solution can usually be injected without encountering elevated intraarticular pressures and horse discomfort. Be aware that beyond 2 mL the horse may start to feel uncomfortable, raise the limb, or even kick. Anecdotal reports of a subtle pop or sudden decrease in pressure have

been attributed to communication between the tarsometatarsal and centrodistal (distal intertarsal) joints. In reality, this most often results from rupture of the tarsometatarsal joint capsule and subsequent deposition of local anesthetic solution (or medication) extraarticularly into the tarsal space and not the centrodistal joint. We recommend using no more than 4 mL of local anesthetic solution or injecting only that amount of local anesthetic solution necessary to develop moderate intraarticular resistance to avoid inadvertent deposition into the intertarsal space. Periarticular extravasation of local anesthetic solution from excessive volume may inadvertently block the nearby lateral plantar nerve and deep branch, potentially alleviating pain associated with the suspensory ligament attachment or other structures. An alternative site for tarsometatarsal arthrocentesis is a medial approach, similar to that described for the centrodistal joint.

The issue of communication between the distal tarsal joints is important from diagnostic and therapeutic standpoints. Studies have shown that the tarsometatarsal and centrodistal joints communicate in 8% to 35% of normal horses.^{59,61,62} Communication between the tarsometatarsal joint (and presumably the centrodistal joint) and the talocalcaneal-centroquartal (proximal intertarsal) and tarsocrural joints was shown to be about 4% in an *in vivo* study, after injection of latex in the tarsometatarsal joint.⁶² Some concern and confusion exist regarding whether or not a single injection into the tarsometatarsal joint also provides analgesia or treats the centrodistal joint. Some clinicians even preferentially inject a large volume of local anesthetic solutions or drugs, hoping to block or medicate the

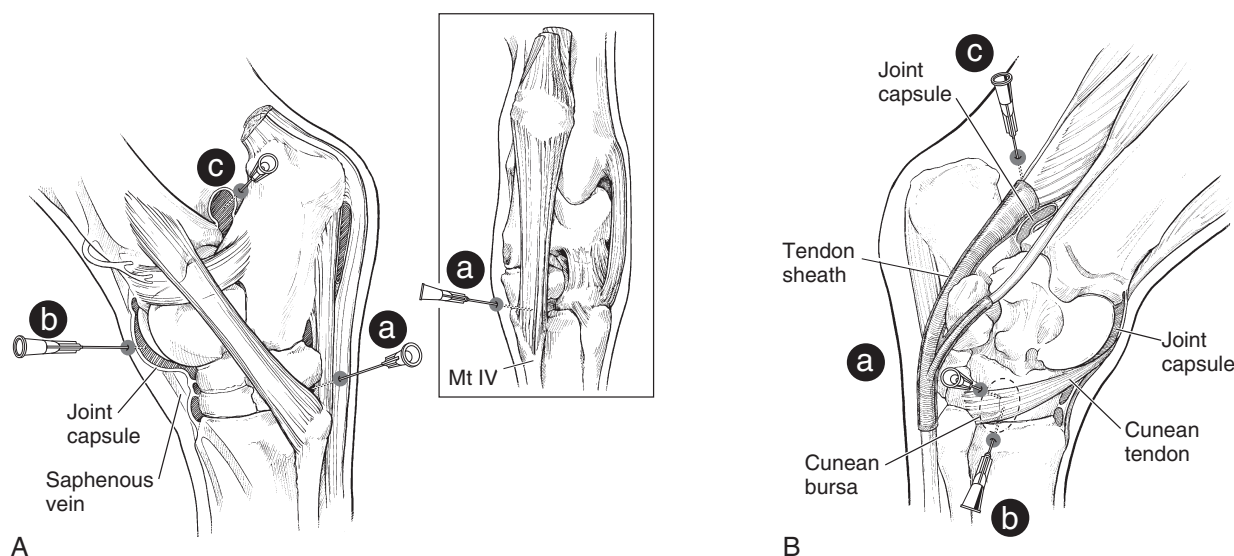

Fig. 10-24 • A, Lateral and plantar (*inset*) views of the left tarsus showing sites for tarsal arthrocentesis. The tarsometatarsal joint is entered by locating the depression just proximal to the proximal aspect of the fourth metatarsal bone (*Mt IV*) and inserting a needle (*a*) in the plantar aspect of this depression, directing it dorsomedially. The dorsomedial pouch of the tarsocrural joint (*b*) is entered either just lateral or medial to the dorsal branch of the saphenous vein or, alternatively, using the plantarolateral pouch (*c*). **B,** Medial view of the left tarsus. The centrodistal joint is entered by placing the needle (*a*) in the depression formed between the fused first and second tarsal bones, the third tarsal bone, and the central tarsal bone, which is at the proximal edge or just slightly distal to the proximal edge of the cunean tendon. The cunean bursa (*dashed ellipse*) is entered by locating the distal border of the cunean tendon and inserting the needle (*b*) under the tendon from the distal aspect or placing it directly through the tendon. The distended tarsal sheath (*c*) can be entered proximal, just caudal to the tarsocrural joint capsule or distal (not shown) to the tarsus.

tarsometatarsal and centrodistal joints. A recent in vitro study found that, although gross anatomic communications exist in only a minority of horses, diffusion of mepivacaine between the distal tarsal joints (as well as between the distal tarsal joints and the tarsocrural joint) occurs with a much higher frequency. Fifteen minutes after injection of 5 mL of 2% mepivacaine into either the tarsometatarsal or the centrodistal joint, mepivacaine was detected in the alternate joint at concentrations >300 mg/L in 64% and 60% of specimens, respectively.⁶³ Whether or not this holds true in the live horse remains undetermined. For that reason, and based on our clinical experience, we believe the clinician should still consider *the tarsometatarsal and centrodistal joints to be separate synovial cavities*. However, it is clear that in some horses analgesia or treatment of the tarsometatarsal joint will relieve centrodistal joint pain. Because the tarsometatarsal joint has distoplantar outpouchings, abolishing pain associated with the proximal suspensory attachment or lesions involving the proximal aspect of the MtIII is also possible when performing tarsometatarsal analgesia. Accurate differential diagnosis for pain involving the lower hock joints and proximal metatarsal region depends on careful interpretation of response to diagnostic analgesia and evaluation of ancillary images.

Centrodistal Joint

Compared with the tarsometatarsal joint, arthrocentesis of the centrodistal joint is relatively difficult. The centrodistal joint is small, and in fact inserting a needle any larger than 22 to 25 gauge into this joint is difficult, even in horses with normal width of joint space. We have tried several alternative sites, including dorsomedial and dorsolateral approaches. Anecdotal reports suggest that the dorsomedial approach, about 1 cm distal to the distal end of the medial trochlear ridge, is a consistent, reliable injection site, but we often enter the proximal intertarsal joint from this approach. An outpouching of the centrodistal joint exists dorsolaterally, but we reasoned that the perforating tarsal artery precluded use of this site in vivo. A recent study described the use of this dorsolateral approach. The site is identified as a point 2 to 3 mm lateral to the long digital extensor tendon and 6 to 8 mm proximal to a line drawn perpendicular to the long axis of the MtIII at the level of the proximal aspect of the MtIV. The success rate for arthrocentesis at this site was equal to that for the traditional medial approach, with purported advantages being improved safety for the clinician and easily identified landmarks. In vivo, iatrogenic injury to the dorsal pedal artery or penetrating tarsal artery was not encountered.⁶⁴

We still preferentially use a medial approach at the distal aspect of, or through, the cunean tendon (medial tendon of insertion of the tibialis cranialis muscle), a structure that can be readily palpated. With a fingertip, the distal edge of the cunean tendon is moved proximally to reveal an ill-defined concavity, the articulation of the fused first and second tarsal bones, with the third and central tarsal bones (see Figure 10-24). This depression is sometimes located in a slightly more proximal location. This injection technique is one of the few commonly performed by standing on the opposite side of the horse. A skin bleb is useful because in most horses inserting a needle directly into the joint is difficult, and numerous attempts may be necessary. A 22- to 25-gauge, 2.5-cm needle is inserted

directly in a lateral direction, horizontally, roughly parallel to the central and third tarsal articulation, perpendicular to the skin. Slight redirection of the needle may be necessary, and in many horses joint fluid is not obtained. If the needle can be inserted to a depth of 1 to 1.5 cm, it is likely properly positioned even if synovial fluid cannot be retrieved. Fluid retrieved in a more superficial location likely indicates penetration of the cunean bursa. In horses in which diagnostic information or therapeutic injection is critical and any question of needle placement exists, radiographs are warranted. A maximum of 4 to 5 mL can be injected. If a larger volume can be comfortably injected, the needle tip is likely in the tarsal space or in the proximal intertarsal joint, or a communication with the tarsometatarsal joint exists. If the injection is difficult to perform, the needle is likely malpositioned in the subcutaneous tissues, or the needle tip is touching articular cartilage. Most clinicians attempt injection of the centrodistal joint after first injecting the tarsometatarsal joint, and in some instances, medication or local anesthetic solution readily flows from the needle. The typical response is, "There must be a communication between the tarsometatarsal and centrodistal joints." However, this clinical finding most often results from inadvertent penetration of the distended medial pouch of the tarsometatarsal joint. Fluid accumulation in the tarsal space from the tarsometatarsal joint injection can cause the same result, if the needle enters the tarsal space rather than the centrodistal joint space.

In horses with advanced osteoarthritis or even in horses with early distal hock joint pain, it may be difficult or impossible to be confident that intraarticular analgesia has been achieved. An alternative approach for providing tarsal analgesia is first to perform sequential, intraarticular analgesia of the tarsometatarsal and tarsocrural joints, and then to perform the fibular and tibial nerve blocks if lameness persists. If lameness abates after the fibular and tibial nerve blocks, a presumptive diagnosis of centrodistal joint pain can be made, assuming other sources of pain abolished by this block can be ruled out.

Tarsocrural Joint

Arthrocentesis of the tarsocrural joint is straightforward and easy compared with some joints, because of extensive and multiple dorsal and plantar outpouchings. In horses with moderate to severe effusion, identifying four distinct outpouchings—the dorsolateral, dorsomedial, plantarolateral, and plantaromedial pouches—is easy. The clinician must keep in mind that the tarsocrural and proximal intertarsal joints communicate through a large fenestration at the dorsal aspect of the joints in adult horses, although in weanlings and yearlings the fenestration often cannot be seen during arthroscopic examination. Any one of the tarsocrural joint pouches can be used, but the most common site of entry is on either side of the saphenous vein, in the dorsomedial pouch (see Figure 10-24). This particular site is preferred in horses without obvious effusion. An alternative site is the plantarolateral pouch. The most consistent site to use is the distal aspect of the dorsomedial pouch, just distal to the medial malleolus of the tibia and medial to the saphenous vein. An 18- to 20-gauge, 2.5- or 4-cm needle is used to deposit 20 to 30 mL of local anesthetic solution into the tarsocrural joint. In horses with severe osteoarthritis of the tarsocrural joint or those with

subchondral bone pain, use of as much as 30 to 50 mL of local anesthetic solution is necessary to abolish pain. In these horses, a false-negative result is common if only 10 to 20 mL of local anesthetic solution is used.

The plantar pouches can be useful alternative sites for arthrocentesis if the dorsomedial pouch is unsuitable, as sometimes occurs with a wound, swelling associated with trauma of the fibularis (peroneus) tertius, or superficial dermatitis. The plantar pouches must be differentiated from distention of the tarsal sheath or other forms of thoroughpin. Although the dorsal and plantar pouches freely communicate, anatomically, flushing from one aspect of the tarsocrural to the other when the horse is in a weight-bearing position may be difficult. Fluid flow between articular surfaces and joint spaces under collateral ligaments is likely restricted when horses are in a weight-bearing position. This same phenomenon occurs in other joint spaces.

Stifle Joint

The three compartments of the equine stifle joint are the medial femorotibial, lateral femorotibial, and femoropatellar joint compartments. Most consider that the femoropatellar and medial femorotibial joints communicate in almost all horses and that the lateral femorotibial compartment is solitary, but recent anatomical studies have shed new light on this time-honored concept. The frequency of communication between the medial femorotibial and femoropatellar compartments was found to be 60% to 74% in normal horses when the injection was performed from the femoropatellar compartment.^{65,66} The frequency of communication was higher (80%) when the injection was performed in the medial femorotibial compartment.⁶⁵ It is important to realize, however, *that the medial femorotibial and femoropatellar compartments did not communicate in all horses*. Inconsistency in communication depending on which compartment was injected was attributed to directionality in the normal foramen or slit between the two compartments (flow easier *from* the medial femorotibial *to* the femoropatellar compartment).

The time-honored assumption that the lateral femorotibial joint is a solitary compartment was also challenged. The lateral femorotibial joint communicated with the femoropatellar joint in 3% to 18% of horses but was indeed solitary in the majority of normal horses.^{65,66} Communication may be more frequent after trauma and certainly after arthroscopic surgical procedures.

Similar to the digit, carpus, and tarsus, there is clinically important evidence that mepivacaine diffuses between the compartments of the stifle joint. The proportion of synovial compartments with mepivacaine concentration >300 mg/L 15 minutes after injection of an adjacent compartment with 10 mL of 2% mepivacaine ranged from 5% to 40%.⁶³ Of note, functional (diffusion) communication between the medial femorotibial and femoropatellar joints was lower than previous estimates (25% to 40% versus 60% to 80%). Volume of local anesthetic solution (10 mL) was considerably lower than is commonly used in clinical practice for intraarticular analgesia of the stifle joints, and it remains undetermined if results of *in vitro* studies translate to actual clinical relevance.

We recommend that each compartment of the stifle joint be injected independently, either sequentially or simultaneously, to avoid confusing results during stifle

analgesia. The variable degree of communication will obviously cause some degree of uncertainty in diagnosis. The same principle is recommended for therapy as well. Needle insertion in the stifle joints is complicated by a natural tendency of horses to react inappropriately to manipulation compared with other areas of the limbs. Horses seem to object to simple palpation of the stifle and may become fractious during arthrocentesis. To avoid excessive manipulation during injection, we have found it useful to attach an extension set to the needle, a procedure that obviates the need to touch the needle or skin when attaching the syringe. If necessary, the extension set may be useful for many diagnostic procedures, particularly in the hindlimbs. In general, 20 to 30 mL of local anesthetic solution are used in each of the medial femorotibial, lateral femorotibial, and femoropatellar compartments. A common misconception is that long needles are needed to perform arthrocentesis of the stifle joint compartments. In fact, some racehorse trainers will insist that “the long needles, Doc” are necessary to achieve success in medicating the femoropatellar joint. If arthrocentesis is performed with the limb in a weight-bearing position, the joint capsules can easily be penetrated with needles no longer than 4 cm. In the flexed position, use of a spinal needle when performing femoropatellar arthrocentesis is necessary. We prefer to have the horse in a weight-bearing position, with the limb slightly ahead of the contralateral limb, a position that allows the clinician to palpate landmarks readily without undue tension on patellar and collateral ligaments.

Arthrocentesis of the medial femorotibial joint is performed at a site located just caudal to the medial patellar ligament, cranial to the medial collateral ligament, and 1 to 2 cm proximal to the medial tibial plateau (Figure 10-25). In a normal horse a distinct depression occurs at this location, but in horses with effusion, a considerable bulge in the joint capsule can be present. An 18-gauge, 4-cm needle is inserted perpendicular to the skin and can be redirected or rotated if synovial fluid is not immediately retrieved. A common mistake is to insert the needle too far distally, and in this position the needle tip enters ligaments or the medial meniscus.

Arthrocentesis of the lateral femorotibial joint is more challenging than for the other two compartments, because the lateral joint pouch is small and located deep within tissue. The site is caudal to the long digital extensor tendon and cranial to the lateral collateral ligament, just proximal to the lateral tibial plateau (see Figure 10-25). These landmarks are easily palpated, but distention of the joint capsule is not, in contrast to the medial femorotibial joint. An 18-gauge, 4-cm needle is inserted horizontally and directed in a slight caudomedial direction. Retrieval of synovial fluid varies, and redirecting or rotating the needle is often necessary. An alternate site can be used, located caudal to the lateral patellar ligament and cranial to the long digital extensor tendon, and just proximal to the tibial plateau.

Arthrocentesis of the femoropatellar joint is most commonly performed at a sub-patellar site and either lateral or medial to the middle patellar ligament. The joint capsule can be easily palpated even in most normal horses, if the horse is in a weight-bearing position. With the horse in a weight-bearing position, an 18-gauge, 4-cm needle is inserted perpendicular to the skin, or directed slightly

Fig. 10-25 • A, Cranial view of the left stifle. The medial femorotibial joint (*a*) is approached from a site between the medial patellar and medial collateral ligaments, about 2 cm proximal to the proximal aspect of the tibia. The femoropatellar joint (*b*) most commonly is injected either between the lateral and middle patellar ligaments or between the middle and medial patellar ligaments (not shown). The needle is directed proximally in this subpatellar position. **B,** Lateral view of the left stifle. The lateral femorotibial joint can be approached by placing the needle caudal to the long digital extensor tendon and cranial to the lateral collateral ligament (*c*) or inserting it between the lateral patellar ligament and the cranial edge of the long digital extensor tendon (*d*). An alternative site for arthrocentesis of the femoropatellar joint (*e*) can be used by passing the needle through the lateral femoropatellar ligament.

proximally, until joint fluid is obtained or the needle tip contacts articular cartilage of the distal femur (see [Figure 10-25](#)). The clinician does not need to angle the needle sharply proximally using this technique. What is sometimes frustrating is that even in horses with obvious femoropatellar effusion, a steady flow of synovial fluid cannot be obtained, and attempting aspiration of fluid with a syringe is seldom helpful, because synovial villi readily plug the needle, making aspiration impossible. Some clinicians perform femoropatellar arthrocentesis with the limb in a non-weight-bearing position, in which case a 9-cm spinal needle is used and the needle is directed proximally, between the patella and distal aspect of the femur. An alternative lateral approach to the femoropatellar joint has been described.⁶⁷ An 18-gauge, 4-cm needle is inserted into the lateral cul-de-sac of the femoropatellar compartment, located about 5 cm proximal to the lateral tibial plateau, caudal to the lateral patellar ligament and the lateral trochlear ridge of the femur. The needle is directed perpendicular to the long axis of the femur until bone is contacted (about 1.5 to 2 cm in most horses) and then is withdrawn slightly until synovial fluid is collected.

Proposed advantages of this approach are a reduced potential for iatrogenic injury to the articular cartilage and more reliable recovery of synovial fluid compared with the subpatellar approach.⁶⁸

Coxofemoral (Hip) Joint

Although the coxofemoral joint is relatively large and the landmarks for needle insertion are consistent, injection is considered to be a daunting task. Few of us perform this injection technique on a regular basis, and depth of penetration makes accurate needle placement difficult. An 18-gauge, 15-cm (6-inch) spinal needle is adequate for all but the largest of draft horses. A needle of this length should be inserted carefully, and if the horse is moving or fractious, it may be necessary to provide sedation. The site is in the angle formed between the long caudal and short cranial processes of the greater trochanter of the femur ([Figures 10-26](#) and [10-27](#)). This site can be difficult to palpate in heavily muscled horses, and ultrasonographic evaluation can be useful to identify the injection site. The most difficult landmark to palpate consistently, but an important one nonetheless, is the cranial process. The site

Fig. 10-26 • Lateral and dorsal (*inset*) views of the left coxofemoral joint. Arthrocentesis of the coxofemoral joint is performed by inserting the needle (*a*) in the angle formed between the caudal and cranial processes of the greater trochanter of the femur. The needle is inserted slightly cranially, distally, and medially just dorsal to the shaft of the femoral neck (*inset*). This view (*b*) shows the seldom used diagnostic technique of synoviocentesis of the trochanteric bursa.

Fig. 10-27 • Arthrocentesis of the right coxofemoral joint. Using an extension set between needle and syringe, a technique that reduces the amount of manipulation necessary during the procedure, facilitates arthrocentesis of this and other joints.

is *between* the two processes, closer to the cranial process and not *caudal* to the trochanter.

Before the needle is inserted, blocking the injection site may be useful. Because the shaft of the needle is handled, sterile gloves are recommended. Needle direction is important. The needle is inserted in a slightly craniomedial direction and slightly distally and directed just dorsal to the femoral neck, until the joint capsule is penetrated. In most horses, a subtle pop can be felt as this occurs. "Walking" the needle off the femoral neck may be useful, using the bone as a guide to the coxofemoral joint. In most adult light-breed horses, this occurs within 3 to 5 cm of the hub of the needle. Synovial fluid is reliably retrieved from the coxofemoral joint, spontaneously or by aspiration. A large volume of local anesthetic solution should not be injected if synovial fluid is not readily obtained, but injecting a small volume and attempting retrieval with a syringe is useful. It is possible inadvertently to inject local anesthetic solution around the sciatic nerve, causing temporary paresis, if the needle is caudally malpositioned, and therefore local anesthetic solution should not be injected if any doubt exists that the needle is correctly positioned. The amount of local anesthetic solution used is 25 to 30 mL.

Most horses are evaluated in 20 to 30 minutes, but in horses with fractures of the acetabulum the clinician should expect only 50% improvement in lameness score, and improvement may be short-lasting (15 to 30 minutes). An alternative ultrasound-guided technique has been described and is particularly valuable in large overweight horses in which the landmarks are difficult to palpate.⁶⁹

ANALGESIA OF HINDLIMB BURSAE AND TENDON SHEATHS

Analgesia of the navicular bursa and DFTs in the hindlimb is the same as in the forelimb.

Cunean Bursa

Occasionally, injecting the cunean bursa is necessary to assess the role of the cunean bursa and tendon in horses with distal hock joint pain, to perform cunean tenectomy, or to medicate the structure. The cunean bursa is seldom the sole source of distal hock joint pain but can play a role, so analgesia or medication of this structure is sometimes combined with other injections.

The cunean bursa is between the distal tarsal bones and the medial branch of the cranialis tibialis tendon (called the *jack tendon* or *cord*) but is seldom palpable (see [Figure 10-24](#)). The distal aspect of the cunean tendon is usually easily palpated, however, by starting at the distal aspect of the hock and sliding the fingertip in a proximal direction. Retrieving synovial fluid is unusual but possible, but during injection the clear outline of the bursa can be seen as it distends. A 20- to 22-gauge needle is inserted deep to the distal edge of the cunean tendon and directed in a proximal direction, and 3 to 5 mL of local anesthetic solution is injected. We prefer this approach, but alternatively the needle can be inserted perpendicular to the skin and directly through the tendon itself until bone is contacted.

Tarsal Sheath

Analgesia of the tarsal sheath is performed to confirm the structure as a source of lameness associated with traumatic and infectious tenosynovitis (although the response may be limited in the face of infection) and various osseous lesions, such as those involving the sustentaculum tali, or unusual exostoses (osteochondroma). The tarsal sheath surrounds the DDFT from a point approximately level with the tuber calcanei and extends to a point 2 to 3 cm distal to the tarsometatarsal joint. Distention of the tarsal sheath is commonly called *thoroughpin*, but occasionally thoroughpin appears as fluid swelling proximal to the tarsus that does not involve the tarsal sheath. The DDFT is located medial to the calcaneus as it crosses the sustentaculum tali. The heavy tarsal retinaculum medially and the calcaneus laterally restrict outpouching of the tarsal sheath to the proximal and distal aspects. The clinician should take care to differentiate tarsal sheath effusion from distention of the plantar pouches of the tarsocrural joint. A 20-gauge, 2.5-cm needle is used to inject 10 to 15 mL of local anesthetic solution.

Calcaneal Bursa

Indications for analgesia of the calcaneal bursa include traumatic and infectious bursitis, tendonitis of the

gastrocnemius or SDFT at this level, and osseous lesions of the tuber calcanei. The bursa is located between the SDFT and tuber calcanei. Proximal to the tuber calcanei, the bursa is interposed between the SDFT and the gastrocnemius tendon. When distended, an unusual clinical finding, the bursa is palpable as medial and lateral outpouchings just proximal to the tuber calcanei. Smaller outpouchings are often discernable just distal to the tuber calcanei but are inconsistent. The bursa can be accessed for injection at any of these outpouchings. A 20- to 22-gauge, 2.5- or 4-cm needle is used to inject 10 mL of local anesthetic solution, after retrieval of fluid for analysis if indicated. Pain may take 20 to 30 minutes to abate in horses with osseous lesions or with severe lameness.

Trochanteric Bursa

Seldom does an indication exist to block the trochanteric bursa, although injections in this region are commonly performed to manage bursitis and muscle pain (see [Chapter 47](#)). The trochanteric bursa is located between the tendon of insertion of the gluteus accessorius muscle and the cranial process of the greater trochanter of the femur (see [Figure 10-26](#); see also [Chapter 47](#)). In normal horses this bursa is small and likely has minimal synovial fluid. Synoviocentesis is performed using an 18- to 20-gauge, 4-cm needle, although in larger, more heavily muscled horses, a longer needle may be necessary. The needle is inserted perpendicular to the skin, directly over the cranial aspect of the greater trochanter until contact with bone is made. We have had difficulty retrieving fluid even in lame horses that have a positive response to analgesia. Generally, 5 to 10 mL of local anesthetic solution are injected until pressure is felt. If local anesthetic solution can be aspirated, the needle was likely in the bursa, but if not, the injection was likely performed in the surrounding tissues.

LOCAL INFILTRATION IN THE FORELIMB AND HINDLIMB

Local infiltration of local anesthetic solution in painful soft tissues or over painful bony swellings can be performed at any location, although some areas deserve special mention. Any localized area of pain, into which a needle can be inserted safely, is fair game for local analgesia.

The clinician must be aware, however, that local infiltration may not provide total analgesia to the region, mostly because the entire nerve supply to the region cannot be blocked. Incomplete analgesia is common in horses with bony lesions, such as bucked shins, because deep pain from the cortex of the McIII is difficult if not impossible to eliminate using subcutaneous infiltration of local anesthetic solution. In most instances, perineural analgesia for this particular condition is preferred. Local infiltration is performed in many horses in lieu of perineural technique, or in horses in which perineural analgesia has localized pain to a general region, but conflicting or numerous clinical problems exist. An advantage of local infiltration is that proprioception is not lost, and horses can be moved at speed for reevaluation after this form of analgesia. Efficacy can be assessed by deep, direct digital palpation, to confirm that the previously identified source of pain was eliminated by local analgesia.

Splints

A common suspected cause of lameness in many horses are exostoses associated most commonly with the second (McII) and fourth (McIV) metacarpal bones or the MtII or MtIV, or in combination with the McIII or MtIII. A 20- to 22-gauge, 2.5- to 4-cm needle is used to deposit 5 mL of local anesthetic solution subcutaneously over the painful exostosis. The needle is slid directly alongside the proliferative lesion, between skin and bone. For splints involving the McII or MtII and the McIV or MtIV, it is important to deposit local anesthetic solution abaxial and axial (between the suspensory ligament and splint bones) to the lesion. In some horses proliferative changes involve only the axial aspect of the McII, MtII, McIV, or MtIV (blind splints), and it is critical to block in this location. In others with primary proliferation between the McII or MtII, McIV or MtIV, and the McIII or MtIII, subcutaneous injection will suffice. When local anesthetic solution is infiltrated on the axial aspect of the splint bones, the palmar or plantar metacarpal or metatarsal nerves are likely blocked, making it possible to abolish pain from a more distal site and leading to misinterpretation of results. In horses with extensive adhesions between the axial aspects of the McII or MtII and the McIV or MtIV, the suspensory ligament pain may be incompletely abolished using a local infiltration technique, and the palmar or plantar nerves and palmar or plantar metacarpal or metatarsal nerves above the site may need to be blocked individually for pain to be abolished.

Suspensory Ligament Origin

Local infiltration or flooding the palmar metacarpal or plantar metatarsal regions at the origin of the suspensory ligament is often done in lieu of perineural analgesia, as described previously. This is also referred to by some as a *subtarsal* or *subcarpal block*. An 18- to 22-gauge, 2.5- to 4-cm needle can be used to distribute 5 to 15 mL of local anesthetic solution in a fan-shaped pattern, usually from a lateral injection site just axial to the McIV or MtIV. It is important to use adequate restraint and have the limb in a flexed position when performing this technique. In the hindlimb an 18- to 19-gauge needle should be used to minimize the potential for needle breakage, should the horse kick during the procedure.

False-positive results, attributed to inadvertent analgesia of palmar metacarpal or plantar metatarsal nerves, penetration of the distal outpouchings of the carpometacarpal and tarsometatarsal joints, or penetration of the tarsal sheath can occur.^{25,56} Compared with high palmar analgesia, the incidence of inadvertent injection of the distal palmar outpouchings of the carpometacarpal joint was highest when local infiltration of the suspensory origin was performed.²⁵ A single injection technique was recently developed for diagnostic analgesia of the suspensory ligament origin in the hindlimb that should both limit the incidence of the previously mentioned complication, and also may be more specific for pain originating from the origin of the suspensory ligament. The technique involves blocking the deep branch of the lateral plantar nerve. The clinician holds the limb with the stifle and tarsus at 90 degrees of flexion and with the digit fully flexed. While the SDFT is deflected medially, a 2.5-cm needle is inserted to the hub, perpendicular to the skin, at a site 15 mm distal to the proximal aspect of the MtIV on the plantarolateral aspect of the limb. The

needle is advanced between the lateral aspect of the SDFT and MtIV, at which point local anesthetic solution is injected.⁷⁰ It is important to understand that from the deep branch of the lateral plantar nerve originate the lateral and medial plantar metatarsal nerves that continue distally, axial to the MtIV and MtII, to provide important innervation to the fetlock joint (see previous discussion). Failure to eliminate fetlock region pain by first performing low plantar analgesia could lead to erroneous interpretation of the results of analgesia of the deep branch of the lateral plantar nerve. If only the deep branch of the lateral plantar nerve is blocked, a diagnosis of proximal plantar metatarsal pain could be made even though fetlock region pain could be the true source of pain causing lameness.

Curb

Curb, the term used for swelling of the distal, plantar aspect of the tarsus, is a complex condition involving SDF tenosynovitis, long plantar desmitis, subcutaneous swelling, or various combinations of these soft tissue injuries (see Chapter 78). Local infiltration can partially abolish pain associated with curb and usually involves depositing local anesthetic solution subcutaneously. Completely blocking deep pain associated with the long plantar ligament or SDFT is not possible without using the fibular and tibial nerve blocks. A tibial nerve block may be more specific.⁵ A 20-gauge, 2.5- to 4-cm needle is used to inject 15 to 20 mL of local anesthetic solution with the limb in a flexed position. Adequate restraint and the help of an assistant are mandatory. Local anesthetic solution is infiltrated subcutaneously along the plantar, medial, and lateral aspects of the swelling, but deep injection into or between the SDFT and long plantar ligament is avoided. The medial injection is most comfortably and safely performed by standing on the opposite side of the horse.

Dorsal Spinous Process Impingement

Infiltration of local anesthetic solution around impinging dorsal spinous processes is a technique that is performed when attempting to confirm or rule out lameness or poor performance associated with back pain caused by impingement or other pain originating from the dorsal spinous processes of the thoracolumbar vertebrae.⁷¹ The horse is usually evaluated under saddle or in harness or on a lunge line, because lameness associated with this condition may be subtle and only manifested under these conditions. The hair along the dorsal midline is clipped, and the site or sites are prepared aseptically. We prefer to use 22-gauge, 9-cm spinal needles, although in most instances shorter needles can easily reach the tops of the dorsal spinous processes. Needles are inserted on the dorsal midline and directed ventrally to the dorsal spinous processes or the interspinous space. Markers placed after scintigraphic or radiographic examination are helpful to determine the precise location for blocking or to administer medication. The interspinous space can be located by redirecting the needle in a cranial or caudal direction. If impingement of the dorsal spinous processes exists, it may be impossible to infiltrate between them, but placing local anesthetic solution around the processes is satisfactory.⁵ Seven to 10 mL (per site) of local anesthetic solution are deposited as the needle is slowly withdrawn, and the horse is reevaluated 10 to 15 minutes later.

Using ultrasound guidance, intraarticular or periarticular injections of the cervical, thoracic, or lumbar facet joints can be performed using a 9-cm spinal needle. Injection techniques for the sacroiliac joints are described in Chapters 50 and 51.

Orthopedic Implants

Occasionally, pain associated with orthopedic implants is suspected to cause lameness. This is most commonly seen in horses after distal McIII or MtIII condylar fracture repair but can occur after repair of proximal phalanx or olecranon

process fractures. Low-grade lameness is most common. Differentiating pain arising from negative interaction of implants with bone or surrounding soft tissue is nearly impossible based on the results of any diagnostic analgesia technique, because innervation to the joint or surrounding tissues is complex. Local anesthetic solution can be injected around screw heads, next to pins and wires or bone plates, and the horse is then reevaluated. Because lameness is often subtle, improvement is often difficult to judge. A combination of clinical findings and those from ancillary diagnostic techniques is used to determine the role of implant pain.

Chapter 11

Neurological Examination and Neurological Conditions Causing Gait Deficits

William V. Bernard and Jill Beech

Differentiating neurological gait deficits from lameness can sometimes be a dilemma for the clinician. Many repeated examinations and ancillary testing may be necessary, and even then experienced clinicians may give varied opinions about the same horse. Lack of definitive diagnostic tests to identify the origin of subtle gait changes, which in some horses may be perceived only by a rider or driver and not visible, promotes diagnoses that are based purely on opinions and individual prejudices. This chapter discusses the examination of a horse with gait deficits caused by disease of either the spinal cord, the most frequently documented cause of neurological gait deficits, or peripheral nerves. The chapter does not consider neurological syndromes characterized by signs of brain dysfunction, such as vestibular, cerebral, and cerebellar disorders. We also refer readers to a review on the equine spinal cord.¹

DIAGNOSIS

History is important but depends not only on asking the appropriate questions but also on many uncontrollable factors, such as how closely, impartially, and astutely the horse has been observed. The time of onset of signs and rate of progression, whether the gait deficit waxes and wanes or is affected by exercise or rest, whether one or more limbs are affected, whether the affected limb varies, what the horse was doing before onset of signs occurred, whether exercise or management has changed, whether the horse has been moved geographically, whether signs occurred after transport, what medications may have been given and any observed effects, and whether other horses

on the farm or in the stable have had any recent illnesses or fever should be determined. It is also important to know if other horses on the same farm have similar clinical signs. For instance, a history of fever, respiratory disease, or abortions in horses in contact with the affected horse would make one suspect equine herpesvirus-1 (EHV-1) infection.

Clinical Examination

The clinician should observe whether the horse displays cranial nerve dysfunction; muscle hypertrophy, atrophy, or asymmetry; muscle trembling; abnormal hoof wear; or abnormal posture. Muscle atrophy may be caused by disease of the ventral horn cells of the gray matter of the spinal cord, peripheral nerve, or the muscle itself; it also can occur with disuse. Palpation can reveal abnormalities such as altered skin temperature, sweating, muscle fasciculations, abnormal sensitivity, or soreness. The horse should be observed on a flat surface, at a walk and trot, and in straight and curving lines. The horse should be evaluated on a surface that allows detection of abnormal hoof flight and placement, toe dragging, or excessive force when landing. The sound of the feet landing should be noted for consistency and loudness. Hard surfaces also may enhance abnormal hyperflexion in horses with stringhalt. Evaluation on a soft surface may be necessary if the horse is unstable or if the clinician is trying to determine whether the horse could have sore feet. Any abnormal head or neck movement associated with limb movement should be noted. It is important to permit normal neck and head movement when the horse is being led. The person leading the horse should hold the horse as loosely as is safely possible. Collapsing or sinking on a limb, knuckling, hyperflexion, spasticity, hesitation in any part of the stride, dragging of a toe, landing excessively hard, leaning to one side, or failing to track straight can indicate a neurological deficit. Various manipulations are used to diagnose whether proprioceptive or motor deficits exist and to localize the lesion. While being led, the horse should be evaluated while stopping and starting from a walk and trot, backing up, circling tightly in both directions, walking while sideways traction is applied and released on the tail, being pushed sideways from a standstill, and walking with its head elevated. Some clinicians also evaluate repositioning of the foot after placing the horse's hoof in an abnormal position. We do not find this particularly helpful because a horse's disposition, age, training, and distractions can

affect its response. A horse with a normal gait may stand with its feet placed in an abnormal position for what seems an abnormally long time. Some clinicians also use wheelbarrowing and hopping reactions.¹ We do not use these tests in mature horses because we believe responses may be inconsistent and difficult to evaluate accurately and safely. Observation of the horse walking or trotting up and down inclines can be helpful in revealing whether the horse “knows where its limbs are” (proprioception) and can adjust limb movement appropriately. It may be helpful to observe the horse while it is being ridden or lunged, and in some horses while it is loose in an enclosure. Watching the horse stop and start, turn, back up, and maintain its balance during many postural maneuvers allows detection of neurological deficits that may not be obvious when the horse is being led. Consider the following:

- Are errors in range of movement of the limb (dysmetria) apparent?
- Is the horse extending its limbs to the full extent, or is the range decreased (hypometria)?
- Does the horse lift its limbs excessively high (hypermetria)?
- Is spasticity or stiffness of movement apparent?

In some horses it is necessary to observe the horse performing its usual activity, providing it is capable. However, gait deficits may be much less apparent at speed than when the horse is walking or trotting slowly. Basically, the clinician is trying to determine whether the horse moves symmetrically and smoothly with normal stride length and height of foot flight appropriate to the breed and use, whether it appears strong and consistently places its feet in the appropriate positions, and whether it moves in balanced harmonious fashion. It is sometimes difficult to determine whether certain postural or gait changes are a result of pain or weakness or are associated with motor or proprioceptive deficits. Is the horse flexing its hindlimbs excessively and holding its croup more ventrally and flexed because of pain or weakness? If the horse is shifting weight between the hind feet, is it because of weakness, as seen, for example, in lower motor neuron disease, or because of pain? When both limbs are affected, manipulation of a limb to try to localize pain may not be possible. Gaited horses can be extremely difficult to evaluate, especially if one is unfamiliar with the specific gaits. Conformation also can confound interpretation of clinical signs. It may be necessary to observe the horse on many occasions and compare its gait before and after exercise. Is the deficit consistent, or does it vary? If it worsens with exercise, is it because of pain or inability to compensate for a neurological deficit as the horse tires? Perineural analgesia may be helpful. Is there palpable evidence of muscle cramping with exercise or an increase in creatine kinase (CK) level, indicating rhabdomyolysis? A variable gait deficit and inconsistent alterations in foot flight or placement are more likely to represent a neurological deficit than lameness; single limb lameness may vary in intensity but usually remains similar in character. Painful and neurological conditions could coexist but may be difficult to differentiate even with use of commonly used analgesics such as phenylbutazone.

If the horse buckles in a limb, especially on turns, is easily pulled sideways by the tail when standing or walking, or trembles its limb, weakness of the extensor muscle groups should be suspected. When the flexor muscles are

weak, the horse is unable to lift its limb normally, and the toe may be worn from dragging. Pushing the horse sideways or trying to pull on the halter and tail simultaneously can reveal weakness. If the horse is weak or has pain in one limb, it is not able to bear weight normally when the contralateral hoof is lifted from the ground. Neck flexion sideways and vertically should be evaluated for ease and range of movement. Skin sensation and the cutaneous trunci reflex and cervical reflexes should be evaluated. Tapping the trunk should elicit contraction of the cutaneous trunci muscle. Abnormalities can delineate a thoracic spinal cord lesion, because afferent input is through the dorsal thoracic nerves and cranially through the spinal cord white matter, and the efferent pathway involves the cranial thoracic motor neurons in the first thoracic and eighth cervical segments and the lateral thoracic nerve. Hypalgesia of the cutaneous trunci as assessed by response to a two-pinch test with a hemostat is rare and occurs only with severe thoracic spinal cord disease.¹ Lack of a cervicofacial reflex (failure of the facial muscles to twitch when the ipsilateral side of the cranial aspect of the neck is tapped) can suggest a lesion in the cervical cord or a branch of cranial nerve VII. If tapping the side of the neck fails to elicit contraction of the cutaneous coli muscle, a cervical cord lesion could exist. If any abnormal response to skin stimulation is detected, the test should be repeated because the horse's disposition can influence its responses. Limb reflexes usually are not used, although patellar reflexes can be elicited in horses. We do not consider the thoracolaryngeal reflex (slap test) to be helpful. Response is inconsistent in horses with cervical spinal cord lesions and may be absent in normal horses. Blindfolding the horse usually is not part of our routine neurological examination unless vestibular disease is suspected. A complete physical examination should always be conducted. In some horses with hindlimb gait deficits, palpation per rectum of the pelvic bones, lumbar region, caudal aspect of the aorta, and iliac vessels may be necessary. Simple observation may not differentiate hindlimb weakness caused by spinal cord disease from that caused by partial aortoiliac thrombosis. Horses that do not “feel right” to the rider yet show no obvious deficits to the observer whether observed saddled or in hand are problematic. It may be necessary to observe a horse from a jog cart or carriage if the gait deficit about which a driver complains is not visible to the bystander. In attempting to differentiate between a musculoskeletal and neurological condition causing a gait deficit in a limb, diagnostic analgesia may be necessary. Obviously, this does not help differentiate pain from lameness emanating from a lesion proximal to the coxofemoral or scapulohumeral joints. A course of nonsteroidal antiinflammatory drugs (such as moderate doses of phenylbutazone for days or even several weeks) may be helpful in determining whether a gait deficit is caused by pain.

Hematology and Serology

In most horses serum chemistry screens and hematological tests are not particularly helpful; however, in horses with a gait deficit caused by an underlying muscle disease, evaluation of aspartate transaminase (AST) and CK levels may be helpful. Stage of training, exercise pattern, and whether the blood specimen was obtained after exercise preceded by a day of rest must be considered in evaluation

of enzyme levels. If a horse consistently has abnormally elevated enzyme levels, then the horse has rhabdomyolysis, and the clinician must decide whether the condition is causing or contributing to the horse's abnormal gait. Plasma CK and AST levels do not increase simply because of muscle atrophy; rhabdomyolysis must occur to increase the enzyme levels in the blood (see Chapter 83). Elevated plasma concentrations of CK and AST in horses that are not being exercised suggest a primary muscle disorder, such as (but not limited to) polysaccharide storage myopathy (see Chapter 83). An elevation in white blood cell count and fibrinogen level indicates inflammation. In our experience, elevation in fibrinogen level is a more consistent indicator of inflammation in the adult horse than is elevation in white blood cell count.

If clinical signs suggest equine lower motor neuron disease, serum levels of vitamin E (α -tocopherol) should be measured; levels of vitamin E have consistently been low in horses with confirmed equine motor neuron disease, unless the horse has been given supplements.² Thus low vitamin E levels may be suggestive of, but are not specific for, equine lower motor neuron disease. Tocopherol concentrations can decrease during winter when horses lack access to green pasture.³ Daily variations in plasma levels may occur.⁴ Low levels also have been reported in clinically normal horses⁵⁻⁷ and in one horse with chronic gastrointestinal disease.⁸ The laboratory that performs the test should be contacted for any specific requirements for submission of samples and to ensure they have an established normal range for vitamin E levels.

Serological testing for antibodies to various infectious agents may be indicated. In EHV-1 infection, detection of an increase in antibody titer is considered diagnostic of the disease. A horse that shows signs of neurological disease secondary to EHV-1 should have an elevated serum antibody titer, and single high titers have been the basis for initial diagnosis in individual horses. Recent vaccination confounds interpretation. Rarely, high titers may be measured in horses with no history of recent vaccination and no obvious clinical signs of EHV-1 infection.

Antibody titers for *Borrelia burgdorferi*, the cause of Lyme disease, sometimes are measured in serum from horses with ill-defined gait deficits. High titers, or rising titers, have been used as a basis for treatment of the disease. A positive titer, however, does not mean the horse has active disease. Because of the geographical variation in exposure to *B. burgdorferi*, titers may vary greatly. Serological surveys in the United States have demonstrated positive test results in 1% of samples from nonendemic areas and up to 68% in endemic areas.⁹⁻¹¹ Reports of horses "responding" to treatment exist,^{12,13} but to date we are unaware of any horses with Lyme disease in which neurological deficits mimic primary lameness. Currently the importance of Lyme disease as a cause of equine gait deficits is unclear.

A Western blot test for the evaluation of equine protozoal myelitis (EPM) was first made commercially available at the University of Kentucky by Dr. David Granstrom.¹⁴ Serological testing for the presence of antibodies to *Sarcocystis neurona* can be used only to indicate exposure to the organism. Through exposure to *S. neurona*, many horses develop antibodies in the absence of clinical disease. Serological surveys in certain areas of the United States have shown that a high percentage of horses have positive

antibody titers. A positive test result does not mean the horse has EPM. A negative test result could theoretically occur in horses with peracute disease or perhaps in severely immunocompromised animals. However, a negative test result usually indicates that disease caused by *S. neurona* is highly unlikely. The test result also could be negative in a horse with signs of EPM if another protozoan, such as *Neospora*, causes the spinal cord lesions. In a U.S. study of several hundred horses with neurological disease, test sensitivity was 89%, but specificity was only 71%, because 30% of horses with other neurological diseases also had antibodies to *S. neurona*. Although the positive predictive value was only 72% in horses with neurological diseases, the negative predictive value was almost 90%, indicating that a negative test result is useful in this population.¹⁴ In one study of 44 horses on a farm sampled for more than 1 year, all horses were seropositive for at least 50 weeks yet showed no neurological signs (see following discussion).¹⁵

Cerebrospinal Fluid Aspiration and Analysis

Cerebrospinal fluid (CSF) can be obtained from either the atlantooccipital or the lumbosacral space. The advantage of lumbosacral centesis is that it can be performed in the standing sedated horse, whereas atlantooccipital centesis requires general anesthesia. Fluid from the atlantooccipital site is considered easier to obtain and not as likely to be contaminated with blood. The atlantooccipital site is identified by palpating the cranial edge of the wings of the atlas. The hair is clipped and the site prepared aseptically. Atlantooccipital centesis is performed at the intersection of the median plane and a line drawn across the cranial edge of the wings of the atlas. In an adult horse, a 9-cm (3½-inch), 18- or 20-gauge spinal needle is directed toward the horse's lower lip with the head held in a flexed position. It is important that the needle remain on the midline as it is advanced, because otherwise it will be too far lateral to enter the subarachnoid space. The needle is initially inserted to a depth of approximately 2.5 cm (1 inch) and then gradually advanced. While the needle is gradually advanced to the subarachnoid space, it should be held carefully to prevent penetrating the spinal cord when advancing through the atlantooccipital membrane and the dura mater. Usually a "pop" is felt as the needle advances through the dura; however, this finding is not consistent and the stylette should be frequently removed to observe for flow of CSF. CSF usually flows from the needle once the subarachnoid space is entered; however, once a substantial depth has been reached (about 5 to 8 cm [2 to 3 inches] in an average-size horse), some clinicians advise gentle and frequent aspiration with a small syringe.

In preparation for aspiration from the lumbosacral space the type and degree of restraint is guided by the horse's behavior, the horse's stability, and the clinician's personal preference. A nose twitch, stocks, sedation, or a combination of physical and chemical restraint are options. We prefer to use light sedation with xylazine, sometimes combined with butorphanol. However, lumbosacral CSF pressure can be transiently decreased up to 15 minutes after administration of a high dose of xylazine (1.1 mg/kg intravenously).¹⁶ The puncture site for lumbosacral centesis is identified by combining several landmarks, realizing that individual variation exists. A line drawn between the caudal edge of the tubera coxae and the intersection with

the midline can be used to locate the lumbosacral space. The lumbosacral space is bordered cranially by the caudal edge of the sixth lumbar vertebra, caudally by the cranial edge of the sacrum, and laterally by the medial rim of the tubera sacrale. The dorsal spinous process of the last lumbar vertebra is lower than the dorsal spinous process of the fifth lumbar vertebra. The V formed by the medial rim of the tubera sacrale is one of the more useful landmarks, and the appropriate site for puncture is within this V. The site should be prepared aseptically, and local anesthetic solution is placed subcutaneously. A small skin stab incision is usually made. The needle is inserted on the midline, at the depression palpated just caudal to the last lumbar vertebra, in the middle of the V formed by the tubera sacrale. A 15-cm, 18-gauge spinal needle is generally adequate for a horse that is 16 hands or less. A 20-cm needle may be necessary in a horse greater than 16 to 17 hands. While the clinician advances the needle, it is critical to remain on the midline. The needle can be advanced until a pop indicates it is advancing through the dura or until the horse responds as the needle stimulates nervous tissue. These responses can be unreliable and occasionally dangerous for the horse, the handler, and the individual performing the centesis. Because horses can react unpredictably (including rearing, bolting, collapsing, or kicking), it is safer to advance the needle gradually until it is near the spinal canal, approximately 12.5 cm (5 inches) in a 15- to 16-hand horse. Once the needle is near the canal, it should be advanced slowly with repeated frequent removal of the stylette and aspiration with a small syringe. The horse may move its tail when the dura is penetrated, but usually minimal reaction occurs. If fluid is obtained but the amount is small, the needle can be rotated 180 degrees. Jugular vein compression for at least 10 seconds (Queckenstedt's test) is thought to elevate intracranial CSF pressure and aid fluid collection, provided flow is not obstructed. If a hemorrhagic sample is thought to be from iatrogenic causes, the syringe can be changed frequently until subsequent aliquots are clear. If fluid is not obtained on the first attempt, the needle is withdrawn and the procedure is repeated slightly cranial or caudal to the original location. CSF samples should be placed in sterile tubes and rapidly processed after collection.

Normal CSF is clear and colorless, and red discoloration indicates hemorrhage. However, normal fluid can sometimes appear mildly hazy when grossly examined, especially in a tube with ethylenediamine tetraacetic acid. Hemorrhage can be iatrogenic or caused by underlying disease. Fluid may appear clear even with red blood cell contamination, and studies indicate that subjective evaluation of spinal fluid is sensitive in detecting blood only when the red blood cells number more than 1200/mcL.^{17,18} Centrifugation of a bloody sample should produce a clear fluid with a pellet of red blood cells on the bottom of the sample tube. If hemorrhage occurred before collection and lysis of cells occurred, the supernatant may be slightly pink or xanthochromic (orange/yellow or yellow). Lysis of red blood cells reportedly can occur within 1 to 4 hours.¹⁹ Xanthochromic CSF results from red blood cell breakdown products (bilirubin) and suggests hemorrhage or vasculitis. A centrifuged xanthochromic sample does not become clear. Turbid CSF may appear with hypercellularity or epidural fat contamination. The latter is not uncommon

with lumbosacral aspirates. Formulas used to differentiate between white cell or protein elevations caused by iatrogenic blood contamination of CSF versus pathological increases have been shown to be unreliable. Contamination with a few thousand red blood cells results in minimal increase in white blood cell count or protein content.¹⁸

The normal reported range for leukocyte counts has been variable; usually a range of 0 to 6/mcL is cited,²⁰ but higher values have been reported.^{21,22} Diversity in techniques can account for different values in normal CSF. Undiluted fluid can be assayed in a hemocytometer, or acidified crystal violet can be added to accentuate the cells.²⁰ It is important that equine reference values be determined in the laboratory the practitioner uses. As previously stated, the cell quality rapidly deteriorates in CSF, and samples for cytological testing should be processed rapidly or a portion fixed in 40% ethanol if processing must be delayed. For morphological and differential evaluation, cytocentrifugation or filtration through a glass fiber membrane filter is the preferred method of processing spinal fluid. In our experience, cell and differential counts are often normal in horses with spinal cord disease. Small lymphocytes and monocytes are normally seen. Neutrophils may be seen with blood contamination or inflammation. Eosinophilia is rarely seen in equine CSF but could occur secondary to parasite migration. Rarely, eosinophils have been seen in samples from horses with protozoal encephalomyelitis,²¹ but frequently spinal fluid from horses with EPM is normal. A relative neutrophilia, with or without an increase in cell count, indicates inflammation, and intracellular bacteria may be seen in horses with bacterial meningitis.

Reported values for protein content of CSF vary considerably among laboratories, probably because of diversity in measurement techniques. A range of 10 to 120 mg/dL is generally acceptable, although some authors consider 100 to 105 mg/dL the high end of normal range.^{20,23} Protein may increase because of vascular leakage (vasculitis), inflammatory lesions, trauma, iatrogenic blood contamination, or intrathecal globulin production. High-resolution protein electrophoresis of CSF has been reported in a small number of horses, but its value as a diagnostic test remains to be determined. Compared with normal horses ($n = 18$), horses with cervical cord compression ($n = 14$) often had a decreased β fraction and post- β peaks.²⁴ However, divergent findings have been reported. Because CK is abundant in neural tissue (and in skeletal tissue and cardiac muscle) and is a large macromolecule that does not cross the blood-brain barrier, measurement was suggested to be a sensitive index of central nervous system lesions. Horses with EPM were reported to frequently have increased CSF CK concentrations, unlike horses with cervical vertebral malformation.²⁵ However, another study showed that the sensitivity and specificity of CSF CK activity are inadequate for diagnostic use. Also, CSF simultaneously collected from the atlantooccipital and lumbosacral sites had disparate values for CK activity, which was not associated with site or other CSF parameters. Contamination of CSF with either epidural fat or dura, which is possible during collection, increases CK activity.²⁶

Albumin is the predominant protein in normal CSF. Elevated albumin concentration can indicate hemorrhage or altered blood-brain barrier integrity. To eliminate

serum albumin as a source of increased CSF protein and albumin, the following albumin quotient (AQ) has been suggested²⁷:

$$AQ = \frac{\text{CSF albumin}}{\text{Serum albumin}} \times 100$$

The AQ cited for normal equine CSF is 1.4 ± 0.04 ,^{23,27} and it was suggested that an increase above reference range indicated blood contamination during sample collection or compromise of the blood-brain barrier. The immunoglobulin G (IgG) index

$$\frac{\text{CSF IgG concentration}}{\text{Serum IgG concentration}} \div \frac{\text{CSF albumin concentration}}{\text{Serum albumin concentration}}$$

was suggested to be useful for differentiating intrathecal IgG production from an increase secondary to blood contamination or increased blood-brain barrier permeability. Normal reference range has been reported to be 0.14 to 0.24.²⁷ However, we do not consider these to be specific, and blood contamination can increase the IgG index without a concomitant change in AQ.¹⁸

Although CSF cell count, cytological examination findings, and total protein concentration often do not represent the extent or type of spinal cord or brain tissue disease, when abnormal, the values can be useful. For example, in central nervous system (CNS) disease caused by EHV-1 infection the fluid may be xanthochromic with a high protein level but normal cell count. This disassociation between elevation in protein level and normal cell count may help differentiate EHV-1 infection from EPM. Also, xanthochromic CSF indicates an alteration in the blood-brain barrier and could explain false-positive CSF immunoblot findings for *S. neurona* in a horse with positive serological test results. Unfortunately, except for EHV-1 infections and meningitis, CSF analysis with currently available tests frequently is not helpful in diagnosing spinal cord disease in horses.

In the United States, the frequency of performing CSF aspiration increased with the introduction of a Western immunoblot test for detecting *S. neurona* antibodies. Although limited data are available, the specificity and sensitivity of the immunoblot test on CSF from horses with clinical signs consistent with EPM were reported to be approximately 90%.¹⁴ However, positive test results have been found in clinically normal horses and in horses with neuropathological lesions other than EPM. Even minute amounts of contamination of CSF with blood can cause the test result to be positive in a horse with high serum antibody levels.¹⁹ When CSF was contaminated by even minute amounts of strongly immunoreactive blood (10^{-3} mL of blood per milliliter of CSF), the fluid was falsely positive even though the AQ was normal.¹⁸ This small amount of blood contamination is grossly undetectable and can correlate with as little as eight red blood cells/mL of CSF. Also, blood contamination, without increasing the AQ, can increase the IgG index. The IgG index is not specific for intrathecal IgG production. Although the red blood cell count may be a more sensitive indicator of blood contamination than the AQ, it does not correlate with the amount of antibody contamination. Minute amounts of highly immunoreactive blood may have a greater impact on CSF Western blot analysis than a greater amount of contamination with blood with low immunoreactivity.¹⁸

Any compromise to the blood-brain barrier regardless of cause allows antibodies to leak into the CSF from the serum, causing a false-positive test result. Although the test for immunoblot *S. neurona* antibodies was reported to have 85% positive predictive value in a study of horses with neurological disease,¹⁴ in the general equine population the test has poor positive predictive value. Many normal horses have positive antibody test results.²⁸ In contrast the negative predictive value for the test is high. With what is currently known, interpretation of positive Western blot results must be made with caution. Negative Western blot test results are generally useful to rule out EPM.

Since the introduction of the original CSF Western blot analysis detecting antibodies to *S. neurona*, other tests have been developed. These tests include a modified Western blot, an enzyme-linked immunosorbent assay (ELISA), and an immunofluorescent antibody test. Large scale critical evaluation of these tests has not been performed. However early indications suggest that all of these tests may have some limitations. The immunofluorescent antibody test cross-reacts with *Sarcocystis fayeri*, therefore resulting in false-positive diagnosis of *S. neurona* infection.²⁹ The ELISA is based on a surface antigen that is missing in some strains of *S. neurona*; therefore, false-negative results may occur.³⁰ For the reasons discussed previously, both the original and modified Western blot tests may produce false-positive results. In conclusion, antibody testing for *S. neurona* infection must be used cautiously and in conjunction with other diagnostic tests in attempts to rule out other causes of neurological disease.

Polymerase chain reaction (PCR) testing detects DNA of infectious organisms and has been applied to CSF. Its value in the diagnosis of EPM is controversial, especially when positive results have been reported on CSF samples that were negative for *S. neurona* antibodies and from horses that did not exhibit overt neurological deficits. We do not find PCR testing for the diagnosis of EPM useful. Use of the PCR technique on CSF has been helpful in diagnosing neuroborreliosis in a horse. Similar to some human cases, the PCR test result was positive yet the CSF had a negative antibody titer.¹²

Radiography

The use of radiographs in evaluating traumatic or infectious injuries, congenital lesions, and developmental malformations of the spinal column is limited by the size of the horse. Radiographs are useful in diagnosing congenital abnormalities of vertebrae, narrowing of intervertebral disk spaces, stenosis of the cervical spinal canal, osteoarthritic changes, osteomyelitis or osseous cysts, vertebral neoplasia, malalignment, and fractures. However, in most mature horses, except for the cervical spine, general anesthesia may be required for adequate radiographs of the spine. Computed tomography (CT) and magnetic resonance imaging have tremendous potential for evaluating the equine central nervous system but also are limited by the size of the horse. At present, except in foals, CT is available only for evaluating the head and cranial midcervical regions. The primary use of radiology in evaluating horses with neurological disease is localization of cervical vertebral lesions or cervical vertebral malformation and diagnosis of cervical compressive myelopathy or stenotic myelopathy (see Chapter 60).

Survey radiology is useful in the diagnosis of cervical vertebral malformation and cord compression but can be misleading. Standing lateral radiographic images of the cervical vertebrae are routinely evaluated to detect vertebral malformation and to measure spinal canal diameter and can suggest the likelihood of cervical compressive myelopathy.^{1,31,32} In horses with cervical compressive myelopathy, malformations that characteristically may be identified include flare of the caudal epiphysis of the vertebral body (vertebral endplate modeling), caudal extension of the dorsal laminae, vertebral nonalignment, and osteoarthritis of articular facets. Modeling of the articular processes of the caudal cervical vertebrae is a common malformation identified in horses with cervical compressive myelopathy and in horses that do not have cervical compressive myelopathy. Radiological interpretation of changes is more difficult in older horses, because obvious changes may be seen, without impingement on the spinal canal. Subjective evaluation of articular facet abnormalities can result in a false-positive diagnosis of cervical compressive myelopathy. Identification of characteristic vertebral malformations supports but does not confirm the diagnosis of cervical compressive myelopathy, and subjective radiological evaluation of a malformation does not reliably differentiate between horses with or without cervical compressive myelopathy. Objective assessment of vertebral canal diameter is a more reliable indicator of cervical compressive myelopathy than the subjective evaluation of vertebral malformation. The minimum sagittal diameter (MSD) is the first described method of assessment of canal diameter based on lateral cervical radiographs.³¹ Determination of canal diameter using the sagittal ratio improves on the original measurements by adjusting for magnification and providing a more accurate adjustment for body size.³² The sagittal ratio measurements were developed using a population of affected (confirmed by myelogram or histopathological studies) versus nonaffected horses.³² The sagittal ratio is determined by dividing the MSD by the width of the corresponding vertebral body. Although a sagittal ratio percent at any cervical vertebra from the third to seventh cervical vertebrae less than 50% is a strong predictor of spinal cord compression, a few horses with no pathological evidence of spinal cord compression have had sagittal ratios of less than 50%. Recently intervertebral measurements of canal diameters were shown to improve diagnosis of cord compression, and addition of intervertebral sagittal ratio measurements was recommended to increase accuracy of plain radiographs.¹

A semiquantitative scoring system for evaluating cervical radiographs in horses younger than 1 year of age has been published. This scoring system used neurological examination alone to determine affected versus nonaffected foals and combined subjective determination of radiographic vertebral malformation and objective determination of canal diameter.³¹ Vertebral canal stenosis is determined by measurement of intervertebral and intra-vertebral MSD. Dividing the MSD by the length of the vertebral body corrects for magnification. Malformation is determined by the subjective assessment of five categories. The most discriminating factors in the semiquantitative scoring system in differentiating affected from nonaffected foals are canal stenosis and the angle between adjacent vertebrae. The disadvantage of the

semiquantitative scoring system is the inclusion of subjective determinations.

Myelographic examination is advised to obtain the best evidence of compression.^{1,33-35} Myelograms also can demonstrate compression from soft tissue masses, which are not evident radiologically, and suggest transverse compression. However, myelography may not be definitive and occasionally is misleading. A study to evaluate myelography critically and compare the results with necropsy findings in a large number of horses has not been done. A diagnosis of cord compression is assumed if a 50% reduction in the width of the dorsal dye column exists. However, the diagnostic criterion of 50% decrease in width of the dorsal dye column is not well documented³⁴ and has been found in horses with no histological evidence of cord compression at the site of dye column decrease. Iohexol is currently the preferred contrast medium for myelography. It is important that the owner understand the advantages and disadvantages (including risks) of a myelogram before the procedure is undertaken.

Electromyography and Nerve Conduction Studies

Recording electrical activity of muscles can indicate whether evidence of denervation or a myopathy exists, although the distinction is not always clear-cut. Electromyographic examination findings in the early stages of disease or injury may be normal. Certain abnormal patterns can indicate denervation. However, depending on the specific areas to be examined, electromyography may require anesthesia or heavy sedation. It may be helpful in identifying abnormal muscles and indirectly the affected nerves. In a standing, awake horse, spontaneous muscle movement can hinder interpretation.

Values for sensory and motor nerve conduction velocities in horses and ponies were reported.³⁶⁻³⁹ Differences in speed of conduction occur in different nerves and horses' sensory nerve conduction velocities are slower than those of ponies.³⁹ However, similar motor nerve conduction velocities were reported for the median and radial nerves of ponies and horses.³⁷ Location of the segment being measured may be important, because distal tapering of nerves may be associated with slower velocity. Skin temperature significantly affects nerve conduction velocity,³⁹ and variability in technique can alter findings. Slower motor nerve conduction velocities were reported in horses older than 18 years of age.³⁶ The procedure usually requires that the horse be anesthetized and, similar to electromyography, should be performed by a skilled person. The technique mainly has been used in research.

Nuclear Scintigraphy

Nuclear scintigraphy has been helpful in identifying lesions in the cervical, thoracic, and lumbar spinal column and pelvic areas not readily evaluated by radiography. It also has been used to evaluate vertebral changes identified radiologically, to determine whether active bone change has occurred. It has revealed hairline fractures and other unsuspected bone lesions in the appendicular skeleton as the cause of gait deficits, which sometimes had been suspected to be caused by spinal cord disease. Scintigraphic imaging from both sides of the horse can differentiate which side may have a lesion. The role of nuclear scintigraphy in diagnosing equine spinal cord disease is limited.

Ultrasonography

Ultrasonography has been used to diagnose aortoiliac thrombosis and to identify soft tissue masses near the spine or deep within muscles. It has also revealed bony proliferation or fractures of the pelvis in horses with obscure gait deficits that were originally suspected to be a result of spinal cord disease.

Virus Isolation

If horses die or are euthanized with neurological signs thought to be caused by viral disease, the spinal cord, brain, or both should be sent for virus isolation. In horses with acute disease, nasal swabs and whole blood samples can be collected.

Immunohistochemistry and Polymerase Chain Reaction Testing

Immunohistochemistry and PCR testing can be used to detect the antigen of certain infectious organisms and are applied most commonly to tissues collected at necropsy but can also be used on affected tissues obtained by biopsy.

SPECIFIC DISEASES AND SYNDROMES

Equine Protozoal Myelitis (EPM)

EPM was first reported in 1974⁴⁰⁻⁴³ and appeared to be the same condition originally reported as segmental myelitis of unknown cause.⁴⁴ It is caused by infection with *S. neurona*. EPM currently appears to be limited to the Western hemisphere. It is particularly of concern in the United States, where in some regions high percentages of horses are infected. The actual number of horses confirmed as having neurological disease from EPM is much lower than the actual number of horses infected, but the disease does have a substantial and serious impact. EPM has not been confirmed in horses younger than 6 months of age, although antibodies were detected in serum from a 2-month-old foal.⁴⁵ A recent comprehensive review of this disease should be consulted for details.⁴⁶ *Neospora* species have been identified as a cause of EPM in horses from the western United States.⁴⁷⁻⁵⁰ CSF testing was positive for *S. neurona* antibodies by Western blot test, and no antemortem features distinguished *Neospora* infection from *Sarcocystis* infection.

The disease caused by *S. neurona* tends to occur in warm, temperate, nonarid areas with resident opossums. The horse is a "dead-end" host, and the disease is not contagious. The life cycle is not completely understood, although opossums have been identified as the definitive host. The proportion of infected horses that show clinical signs is low. This disease can cause gait deficits affecting one or all limbs and may be difficult or impossible to differentiate from musculoskeletal or other neurological diseases. Signs ascribed to EPM by veterinarians in the United States have been seen in horses in the United Kingdom, where horses have no known exposure to the organism.¹ Infected horses and horses with confirmed EPM seen in Europe, Asia, or South Africa have been imported from the Western hemisphere.⁴⁶ Horses frequently show asymmetrical deficits and may have focal or multifocal muscle atrophy or cranial nerve deficits. Horses may have profound or mild motor or proprioceptive gait deficits, and onset of signs can be acute or chronic, with slow or rapid progression. It may

be difficult or impossible to differentiate subtle neurological deficits from those caused by subtle lameness or musculoskeletal pain. Behavior may change. Focal sweating may occur. Diagnosis is based on clinical signs and history, by eliminating other potential causes by radiography and other diagnostic tests, and by testing of serum or CSF for antibodies to *S. neurona*. No definitive antemortem test exists, although absence of serum antibodies to *S. neurona* makes it highly unlikely that a horse has EPM. If a horse demonstrates classic signs (e.g., asymmetrical motor deficits and muscle atrophy in the hindlimbs, asymmetrical motor deficits in one or more limbs, a limb deficit combined with cranial nerve deficits not deemed caused by peripheral nerve trauma) and has no other organ dysfunction, we would treat the horse for EPM if it has been in the United States and serological findings are positive. We would forgo CSF testing for reasons outlined earlier.

To date, drugs used to treat EPM have been a combination of trimethoprim-sulfa (sulfadiazine or sulfamethoxazole) and pyrimethamine, or sulfas and pyrimethamine, diclazuril, toltrazuril, and nitazoxanide. Because no definitive antemortem test exists to confirm the disease, evaluation of response to therapy is problematic, especially because the clinical syndrome as treated is so variable and often poorly defined. To date, no treatment trials of experimental infections have been reported. Confounding assessment of drug response is the fact that experimentally infected horses develop clinical signs that decrease over time, despite receiving no treatment.⁵¹ Numbers of organisms ingested, virulence factors, and the horse's own immune status (which depends on heredity, previous exposure to *S. neurona*, stresses such as transport and parturition, lack of adequate nutrition, and other factors) all presumably can affect development of and recovery from the disease. In the United States the most widely used drug combination is one of the sulfa drugs and pyrimethamine. Because pyrimethamine reaches higher concentrations in the CSF and neural tissue, it is considered superior to trimethoprim. The usual dosage regimen is 20 mg of sulfadiazine per kilogram once or twice daily and 1 mg of pyrimethamine per kilogram once daily, both by mouth for at least 2 to 3 months. Diarrhea occasionally occurs in horses treated with trimethoprim-sulfamethoxazole, and anemia and leukopenia have been observed in some horses receiving 1 mg of pyrimethamine with sulfas per kilogram twice daily. Whether horses require such a prolonged course of treatment or continued high levels of pyrimethamine is unknown. Earlier treatment regimens used a lower dose, but to our knowledge no observations comparing dosages have been reported. A syndrome of bone marrow aplasia and hypoplasia, renal nephrosis or hypoplasia, and epithelial dysplasia was reported in three foals born from mares given sulfonamides, trimethoprim, pyrimethamine, vitamin E, and folic acid during gestation. The authors of that report suggested that administration of the folic acid reduced absorption of active folic acid and, combined with the folic acid inhibitors (trimethoprim and pyrimethamine), induced folic acid deficiency and lesions in the foals.⁵² We do not routinely add supplements for horses being treated with trimethoprim or pyrimethamine, but if sequential blood tests indicate anemia or leukopenia, the horse should be given folinic acid, a form of bioactive tetrahydrofolate. Folic acid should not be used because it

is poorly absorbed in the horse, conversion to its active form is prevented by the dihydrofolate reductase inhibitors pyrimethamine and trimethoprim, and it can competitively decrease absorption of the active form of folic acid.^{46,52}

Diclazuril, a coccidiostat, has anti-*S. neurona* activity in cell cultures infected with *S. neurona*⁵³ and has been used to treat horses with suspected EPM.⁵⁴ It is absorbed quickly after feeding. Dosage and therapeutic efficacy are being evaluated. Toltrazuril, like diclazuril, is a triazine-based anticoccidial drug. Because the drug has good lipid solubility and oral absorption and is absorbed into the CSF, it has potential for treating EPM.⁵⁵ Ponazuril, a metabolite of toltrazuril, has in vitro activity against *S. neurona*.⁵⁶ Ponazuril appeared to have favorable clinical results in a multicenter treatment study.⁴⁶ The drug has undergone U.S. Food and Drug Administration (FDA) testing, has been approved, and is marketed under the trade name Marquis. Label recommended dosage is 5 mg/kg administered once per day orally. Studies have shown that Marquis has a wide range of safety. The lack of complicating side effects has led to numerous nonlabel dosage regimens. Some of these dosage regimens include double doses for the first 3 to 5 days of therapy, loading doses of 7 times the recommended dose followed by twice the recommended dose for the duration of therapy, and high doses given once weekly or monthly. These nonlabel uses have not been critically evaluated and should be used with caution.

Nitazoxanide kills *S. neurona* in cell cultures and has been tested in a field trial. Safety studies showed lethargy at twice the recommended dose and illness and death at four times the recommended dose. Gastrointestinal upset can be a complication of nitazoxanide therapy. Concurrent administration of a vegetable oil (corn oil) with nitazoxanide appears to increase small intestinal absorption and reduce gastrointestinal upset. Manufacturers have also recommended starting therapy with a reduced dose for several days. In seven horses with clinical signs compatible with EPM and positive immunoblot results for *S. neurona* antibodies in the CSF, clinical signs improved in six horses by the end of the trial (85 to 140 days).⁵⁷ Clinical signs recurred in two horses when treatment was stopped, but signs improved when treatment was reinitiated. Another report described two horses with a diagnosis of EPM that improved after 28 to 42 days of treatment with 50 mg of nitazoxanide per kilogram once daily.⁵⁸ Anorexia and depression were reported as side effects.⁵⁸ The CSF remained positive for *S. neurona* antibodies. Until more information is available about this drug, we do not recommend its use. Although nitazoxanide received FDA approval and was marketed as Navigator, recently the drug was taken off the market presumably as a result of gastrointestinal complications.

To our knowledge, no evidence shows that concurrent use of immune stimulants, oral antioxidants, and antiinflammatory drugs has any beneficial effect. The use of corticosteroids is controversial, because some clinicians claim corticosteroid administration can exacerbate infection. Severity of neurological signs in horses infected with *S. neurona* reportedly was increased by corticosteroids,⁵⁹ but in another study of induced disease, signs were less severe in horses given corticosteroids.⁶⁰

Providing an accurate prognosis is difficult, given the inherent diagnostic problems. Some horses that recover or respond to treatment may not have EPM, and others may

recover spontaneously. Economic factors influence duration of treatment and time allowed for convalescence. Even when a severely affected horse improves dramatically, if recovery of function is not complete, a return to previous performance levels is not possible. Signs also may recur in the same horse; whether this is caused by recrudescence of infection or reinfection is unknown. We usually give a guarded prognosis for full recovery of horses showing moderate gait deficits compatible with EPM.

Because the exact life cycle and natural intermediate hosts are unknown, definitive recommendations for control of the disease are difficult. Because the opossum is the definitive host and sheds sporocysts, which the horse ingests, fecal contamination of feedstuffs or water sources by this animal should be prevented. The role of other intermediate mammalian hosts is unclear. The efficacy of a recently introduced vaccine remains to be determined.

Cervical Spinal Cord Compression

Cervical vertebral malformations of various types have been described as the cause of cord compression and neurological signs.^{1,61,62} Occasionally it may be difficult to decide if a horse is mildly affected by cervical cord compression or is bilaterally lame in the hindlimbs. Mildly affected horses may show only a slightly stiff, stabbing gait at a walk and trot, only mild circumduction of the outside hindlimb when turning, and equivocal hindlimb dysfunction at a canter. Horses with bilateral osteochondrosis dissecans of the hocks or stifles may show similar signs but usually also have joint capsule distention. Thorough lameness and neurological examinations and radiographs are needed. With more severe compression, the gait deficits increase. Circumduction may be severe, and the horse may strike the distal aspect of the limb with the opposite hoof, causing hair loss or wounds from interference. A horse may lose balance or fall, especially when backing up or turning. If the caudal cervical spinal cord is compressed, thoracic limb motor deficits and hypometria, frequently asymmetrical, may occur. The horse may severely scuff or drag its toes and have abnormal hoof wear. Occasionally, substantial bony proliferation at the synovial articular facets can result in neck stiffness and decreased ability to turn in one direction. Cervical muscle atrophy is rare but can occur if the nerves or lower motor neurons are affected. An affected horse usually lacks hindlimb impulsion and may have a somewhat stiff, bouncy canter. The horse frequently is imprecise when stopping, and the hindquarters may sway or bounce. When compression of the cranial cervical spinal cord occurs, the horse may hold its neck and head higher than normal, in an extended position, and in horses with severe clinical signs all limbs may be affected. Signs may occur suddenly or have a more gradual onset, and progression is variable.

Various vertebral abnormalities have been reported in young horses, but clinical signs can be delayed, even when radiographs reveal chronic lesions. We suspect that trauma may cause a preexisting lesion to become clinically relevant. If a horse with vertebral malformation falls, acute spinal cord compression can occur. Acute cervical spinal cord compression caused by trauma can cause tetraparesis or recumbency, but signs may be delayed in the initial stages after injury and may become apparent only when muscle spasms subside, the unstable fracture displaces,

or progressive hemorrhaging is present. In the neck the occipitoatlantoaxial and caudal cervical regions are predilection sites for spinal cord injury.¹ Synovial cysts may also cause severe sudden signs of spinal cord compression, often asymmetrical and sometimes intermittent.¹ The diagnosis of synovial cysts is usually made at necropsy.

Diagnosis of cervical cord compression is based on radiography and myelography. Numerous types of vertebral abnormalities have been described. Management depends on the nature of the lesion, severity of clinical signs, intended use of the horse, and financial considerations. Horses affected by cervical vertebral malformation and cord compression at less than a year of age may improve when exercise and energy intake are restricted.⁶³ Although no controlled studies of a paced diet and restricted exercise program have been conducted, clinical experience supports its use in young horses with radiological evidence of cervical vertebral malformation.^{1,63} This treatment is not helpful for young horses with very severe stenosis, for defects such as occipitoatlantoaxial or other cranial cervical malformations, or for older horses. Prognosis with conservative management is poor. Surgical fusion of vertebrae is indicated in some horses and has been used successfully.^{62,64,65} This subject is discussed in Chapter 60.

Equine Degenerative Myeloencephalopathy and Neuroaxonal Dystrophy

Horses mildly affected by equine degenerative myeloencephalopathy and neuroaxonal dystrophy may be misdiagnosed as being lame. Clinical signs may be somewhat similar to those of cervical spinal cord compression. Because no definitive antemortem test exists, clinical diagnosis is based on clinical signs, sometimes supported by the presence of other affected horses on the same farm or in the same family.

Equine degenerative myelopathy is thought to be a vitamin E deficiency, with a likely genetic predisposition.^{66,67} Neuroaxonal dystrophy appears to have a genetic basis in Morgan horses.⁶⁸ Various breeds and also Przewalski's horses and zebras can be affected, and no geographical restriction is apparent. When horses are affected at a young age (i.e., <6 to 12 months old), signs are more severe and progressive than when signs are first noted in horses 2 years old or older. However, because signs can be mild and only slowly progressive, owners may not be aware of the abnormality. When a severely affected horse is identified on an individual farm, other, more mildly affected horses are often found on the same premises or among relatives. Signs tend to be most noticeable in the hindlimbs. Affected horses usually lift the hind feet too high and slap them down on the ground and frequently lift the hoof toward the midline and then place it more laterally. The gait is jerky and asynchronous and sometimes ataxic, with excessive sideways sway of the hindquarters. Interference may occur, with a hind hoof hitting the opposite hind fetlock or pastern region. The horse may have a jerky foot placement when stopping and may pivot on the hindlimbs when turning. Severely affected horses may show forelimb ataxia and weakness of all limbs. The gait lacks impulsion. Occasionally, middle-aged horses are examined because of inability to perform at collected gaits with impulsion and precision. No musculoskeletal cause is found, but the hindlimb gait is characteristic of mild equine degenerative

myeloencephalopathy or neuroaxonal dystrophy. Mildly affected mature horses appear to function without substantial progression of signs. No ancillary diagnostic test confirms the disease. Vitamin E supplementation (5000 to 6000 units by mouth daily) has been used to treat affected horses, with some, but not total, improvement reported.⁶⁹ Horses at risk for the disease should be given vitamin E supplements. Supplementation on farms with a number of affected horses was associated with a subsequent decrease in the incidence of disease.⁶⁶ Mares and foals should have access to grass pasture, because lack of access to green pasture has been identified as a risk factor.

Equine Lower Motor Neuron Disease

Equine lower motor neuron disease has been diagnosed in many countries.⁷⁰ Older horses and those lacking access to green pasture appear to be at risk to develop equine lower motor neuron disease. The disease is thought to be caused by deficiency of antioxidant activity in the central nervous system, leading to degeneration and loss of lower motor neurons in the brainstem and spinal cord.⁷¹ Affected horses lose muscle mass and have generalized muscle trembling, which may be more severe in the triceps and quadriceps and is exacerbated by transport. Other clinical signs include stiffness, shifting of weight between the hindlimbs, standing with all feet excessively under the body, excessive sweating, holding the tail elevated and trembling, long periods of recumbency, and sometimes excessively low head carriage. Trembling disappears when the horse lies down. Although the gait may be choppy, the horse has no lameness or ataxia. Horses move better than they stand, and therefore the condition is unlikely to be confused with lameness. Muscle atrophy may be profound. Ophthalmoscopic examination of horses with chronic equine lower motor neuron disease may reveal abnormal pigment deposition in the tapetum with a horizontal band of pigment at the tapetal-nontapetal junction.⁷² Diagnosis is based on clinical signs and low serum vitamin E concentrations in unsupplemented horses or biopsy of the sacrocaudalis dorsalis medialis (dorsolateral coccygeal) muscle. Affected horses that have not been given vitamin E usually have serum vitamin E concentrations less than or equal to 1 mcg/mL.⁷³ Biopsy of a branch of the spinal accessory nerve, which had a high specificity and sensitivity in diagnosis of equine lower motor neuron disease, has been replaced by the muscle biopsy, which is technically much easier, can be performed in the standing horse, and has a similar diagnostic specificity and sensitivity.⁷⁴ However, false-positive test results can occur in horses that have had "tail blocks."⁷⁴ The dorsolateral coccygeal muscle is ideal for biopsy because it contains a high percent of type I oxidative fibers, which are the main muscle fibers affected by the disease. Other muscles with a high proportion of type I fibers are not accessible for biopsy. Most limb muscles have high percentages of type II fibers and are not suitable for diagnosis of the disease.

Oral vitamin E supplementation (6000 to 10,000 units by mouth daily) improves horses, and green pasture is also helpful. However, athletic ability may remain impaired.⁷¹

Equine Herpesvirus 1 Infection

Neurological disease caused by EHV-1 can occur in individual horses or as an outbreak. Ataxia is variable but

usually symmetrical. The hindlimbs are more severely affected, and recumbency can occur. Signs occur acutely and usually stabilize within 24 to 48 hours. Because this condition is unlikely to be confused with lameness, it is not discussed further and readers are referred to a review.¹

Miscellaneous Diseases of the Spinal Cord

Spinal cord disease from migrating parasites could manifest as an asymmetrical gait deficit. Incidence appears to vary geographically, and clinical signs reflect the path of migration. Antemortem diagnosis is usually not possible, although eosinophilia in the CSF supports the diagnosis. Various parasites including *Setaria* species, *Halicephalobus* (*Micronema*) *deletrix*, *Hypoderma*, and *Strongylus* species have been identified. Treatment includes antiparasitic and anti-inflammatory drugs.

Vertebral osteomyelitis, neoplasia, and diskospondylitis are rare causes of spinal cord disease. Signs reflect location of the lesion, which may be confirmed by radiography or scintigraphy. CSF may reflect the disease condition if it extends through the dura. Traumatically induced diskospondylitis has been described and may be difficult to differentiate from bacterial diskospondylitis.^{1,75} Spinal cord traumas may occur directly or from instability of intervertebral joints. External trauma can affect any horse, and clinical signs reflect the site of the lesions. Three predilection sites for injury are the occipitoatlantoaxial region, the caudal cervical region (the fifth cervical to the first thoracic vertebrae) and midthoracolumbar region.¹ Clinical signs may initially be mild or peracute, and some horses develop severe progressive signs. It is often not possible to perform an adequate or accurate neurological examination on, or form a prognosis for, an acutely injured horse. Initial treatment includes first aid care, sedation if needed, and the administration of analgesics, anti-inflammatory drugs, and mannitol. Radiographs can be useful, depending on site of injury and size of the horse. Repeated neurological evaluations are used for prognosis.

Peripheral Nerve Injuries

Except for stringhalt and radial nerve injury, peripheral nerve diseases affecting the gait are rarely diagnosed. Suprascapular nerve injury *by itself* does not alter the gait but results in atrophy of the supraspinatus and infraspinatus muscles (Sweeney; see Figure 6-20).⁷⁶⁻⁷⁸ However, injury to the nerve usually occurs with more general trauma to the region such as a collision or fall. This type of injury frequently can lead to damage to other nerves of the limb and soft tissue structures. If other nerve roots of the brachial plexus are simultaneously damaged, the shoulder joint may be unstable and may subluxate laterally. The horse may circumduct the limb during protraction. Rest and anti-inflammatory drugs are usually used. Several surgical procedures have been advocated for suprascapular nerve injury.⁷⁹

Radial nerve paresis or paralysis is recognized, usually secondary to trauma. Horses with radial nerve paralysis cannot flex the shoulder joint or extend the elbow, knee, fetlock, or interphalangeal joints (see Figure 5-14). The dorsum of the toe rests on the ground, and the elbow is dropped. Severely affected horses have difficulty rising and often collapse on the limb if it bears weight. More mildly affected horses may advance the leg by flinging or jerking it forward from the shoulder. Evaluation of skin sensation

may not be helpful. Atrophy of the triceps and other limb extensor muscles occurs after 2 weeks, and denervation potentials can be found on electromyographic examination 3 to 4 weeks, or sooner, after radial nerve injury.^{79,80} Because of the difficulty of knowing whether the gait deficits result solely from radial nerve injury or muscle damage, an accurate prognosis can be difficult in horses with acute clinical signs. Signs of radial paralysis occurring after recumbency or general anesthesia are probably caused by ischemic myopathy, with possible ischemic neuropraxia, and these horses generally recover. Prognosis depends on the cause and extent of radial nerve injury, neither of which may be identified. Prognosis is obviously better in horses that are less severely affected and those that show early signs of improvement. However, some severely affected horses completely recover. Prognosis is worse if rapid severe atrophy of extensor muscle occurs. Signs of radial nerve dysfunction may be associated with trauma to caudal cervical or cranial thoracic nerve roots secondary to an injury to the head of a rib; other nerves and muscles may also be affected. Signs of radial nerve dysfunction can also occur from lesions in the caudal cervical and cranial thoracic ventral gray matter, but other signs of spinal cord disease usually coexist, especially in EPM. Physical therapy, including splinting to avoid flexural deformity, is very important, and electrical stimulation of muscles may also help prevent atrophy. Irreversible fibrosis and contracture are likely without intervention.

Lesions in the nerves supplying the flexor muscles of the thoracic limb are extremely rare, although signs of dysfunction can accompany brachial plexus or spinal cord lesions.⁷⁷ If the ulnar nerve is sectioned, the horse may move its foot in a jerking fashion with decreased flexion of the fetlock and carpal joints. When the median nerve is cut, the horse drags the toe because of decreased flexion of the fetlock and carpus. Hypalgesia of the medial aspect of the pastern occurs, whereas with ulnar neurectomy, hypalgesia of the lateral metacarpal region occurs.^{77,79} After neurectomy of the proximal musculocutaneous nerve, the horse drags its toe because of decreased elbow flexion. Because natural disease syndromes affecting these nerves are not described, prognosis is difficult because gait deficits improve with time after neurectomy.⁷⁹

If the femoral nerve is damaged, the horse cannot extend its stifle and rests the leg in a flexed position. The hip is lower than the opposite limb, and the horse cannot support weight normally or at all when walking. When both limbs are affected, the horse will appear crouched and have great difficulty rising. The patellar reflex is absent or depressed, and with time the quadriceps muscles atrophy. Damage to the nerve has occurred during general anesthesia with horses positioned in dorsal or lateral recumbency (usually with the affected limb having been positioned uppermost) or after overextension of the limb, after pelvic or femoral fractures, or in association with space-occupying masses impinging on the nerve.^{79,81,82} Lesions in the spinal cord ventral gray matter or nerve roots at the L5 or L6 lumbar vertebra can also cause signs of femoral nerve paralysis. Horses with patellar fractures and subsequent inability or reluctance to bear weight on the affected hindlimb may mimic those with femoral nerve injury.⁸² Complete neurological evaluation to detect other deficits may be difficult if signs of femoral nerve paralysis are severe. Because the

condition is rare and rhabdomyolysis and postoperative myopathy can mimic the signs of femoral nerve damage, giving a prognosis is difficult. Antiinflammatory drugs are usually used. Most horses with postanesthetic femoral nerve paresis make a complete recovery.⁸²

Signs of paresis or paralysis of the sciatic nerve can occur in horses with pelvic fractures, with deep muscle injections in foals, or with spinal cord lesions affecting the ventral gray matter or nerve roots of the fifth lumbar to third sacral nerves. Signs reflect flexor muscle weakness. The horse can support weight on the limb if the hoof is placed flat on the ground under the pelvis. Otherwise, the horse stands with the hock and stifle extended and the dorsum of the hoof on the ground behind it. When the horse walks, it drags or jerks the limb forward. With time all muscles distal to the stifle and those of the caudal aspect of the thigh atrophy. The prognosis is very poor if the nerve is severed. If the fibular (peroneal) nerve is damaged (usually because of blunt trauma), the horse cannot extend the fetlock and interphalangeal joints or flex the tarsus normally. At rest it stands with the hoof behind it, resting on its dorsal surface. If the hoof is placed flat on the ground under the horse, the horse can support weight. When the horse moves, it drags the foot cranially, then jerks it caudally, sliding it on the ground. Skin sensation is decreased over the dorsal and lateral aspects of the tarsus and metatarsal region. With time, muscle atrophy in the craniolateral aspect of the crus can occur. Treatment involves support and protection of the distal limb. Electrical stimulation of muscles might help prevent muscle atrophy. Many horses recover with time. Gait had returned to virtually normal within 3 months of experimental transection of the fibular nerve.⁷⁹ Tibial nerve injury is uncommonly diagnosed, but a stringhalt-like gait has been described. When walking, the horse overflexes the limb and drops the foot straight to the ground when it reaches the end of the cranial phase of the stride. The gastrocnemius muscle reportedly atrophies. The horse stands with the fetlock flexed or partly knuckled, the tarsus flexed, and the hip lower than that of the unaffected leg.⁸¹ Obturator nerve damage, which can occur after foaling, results in signs varying from abduction or circumduction and stiffness of the affected limb when walking to paraplegia. Prognosis depends on severity of signs, whether both limbs are affected, and whether adequate supportive care can be provided.

Stringhalt is easily recognized from its exaggerated flexion of the hock, which can result in a bizarre hopping, jerking, and propulsive gait when both hindlimbs are affected (see Chapter 48). Horses may be so severely affected that they “freeze” in the abnormal position or are very reluctant or unable to move, particularly in those with bilateral stringhalt. They may strike the ventral abdomen with the hoof. The gait usually is worse when the horse is walking on a hard surface and when it is anxious or frightened. Horses with mild signs may show the exaggerated hock flexion only when backing up or turning or during the first few strides after walking from a standstill. Atrophy of the distal limb muscles may occur in horses with chronic stringhalt. Spasticity, toe scuffing, and stumbling of the thoracic limbs and left laryngeal hemiplegia have been described in some affected horses.^{83,84} A distal axonopathy of peripheral nerves has been described.^{85,86} The condition can be sporadic or occur in outbreaks. The cause frequently is unknown, especially when only one horse is affected. Outbreaks have been associated with particular pastures, and mycotoxins are a suspected cause.^{83,84} Lathyrism can also be a cause. Phenytoin and baclofen have been used with some success to decrease clinical signs.^{87,88} Tenectomy of the lateral digital tendon has also been used. The course is variable, and some horses recover spontaneously. However, because it is difficult to predict which horses will recover, the prognosis is guarded, especially in horses with severe clinical signs or in single horses unassociated with a pasture outbreak.

Shivers is somewhat similar to stringhalt, and the origin and pathogenesis are unknown (see Chapter 48). Affected horses tremble one or both pelvic limbs, primarily when backing up or lifting a hoof, and they elevate the tail. Some affected horses cannot stand to have the hooves trimmed, even though the hindlimb gaits are relatively normal and otherwise functional. The clinical course seems variable, and the disease is thought to be progressive, at least in draft breeds.⁷⁹ However, we have seen affected horses remain relatively static and functional, although hoof care can be difficult because of the inability to stand for the farrier. A group of horses exists with mild hindlimb deficits resembling a combination of stringhalt and shivers. Although these horses may continue to be functional for riding, the gait disability impairs dressage performance. The cause usually is undiagnosed.

Chapter 12

Unexplained Lameness

Sue J. Dyson

Lameness diagnosis is a never-ending challenge, even for an experienced clinician, because despite a logical and thorough investigation it still may prove difficult to reach

a satisfactory conclusion. This chapter discusses some of the reasons why a definitive diagnosis may remain elusive. In some horses it may be possible to isolate the source of pain reasonably accurately, but it may not be possible to determine the cause of pain. In other horses the source of pain cannot be determined (see Chapter 97).

FALSE-NEGATIVE RESPONSES TO DIAGNOSTIC ANALGESIA

A false-negative response to local analgesic techniques may occur for a variety of reasons, including the following:

- Inaccurate injection
- Inadequate time for the local anesthetic solution to be effective
- Failure to appreciate improvement in the lameness
- Very severe pain
- Failure to alleviate subchondral bone pain after intraarticular injection
- Extraarticular pain
- Aberrant nerve supply
- Failure, in an unshod horse, to appreciate the extent of foot soreness contributing to lameness
- Failure to appreciate the degree of lameness fluctuation within an examination period
- Failure to abolish pain associated with a neuroma
- Neuropathic pain

The following are common case examples:

1. It is misleading to conclude that pain does not arise from the centrodistal and tarsometatarsal joints and the central and third tarsal bones after a negative response to intraarticular analgesia of the centrodistal and tarsometatarsal joints. Intraarticular analgesia has only a limited ability to alleviate subchondral bone pain. In moderate to advanced osteoarthritis, subchondral bone pain is a clinically significant contributor to pain. Hock pain may be missed if it is concluded that a negative response to intraarticular analgesia precludes the existence of hock pain and if there is a failure to desensitize the hock region using regional analgesia. It should also be recognized that perineural analgesia of the fibular and tibial nerves may result in only partial improvement in lameness associated with moderate-to-severe osteoarthritis of the centrodistal and or tarsometatarsal joints.
2. Laminitis, a fracture of either the distal phalanx or the navicular bone, and a subsolar abscess are all common causes of severe foot pain. Desensitization of the foot by perineural analgesia of the palmar (plantar) nerves at the level of the proximal

sesamoid bones may have a negligible effect or result in only mild improvement in lameness. Foot pain in a hindlimb is often more difficult to alleviate than in a forelimb. If clinical signs point to foot pain, but apparent desensitization of the foot fails to markedly alter the lameness, further investigation of the foot should be performed with other means (e.g., radiographic examination).

The horse in [Figure 12-1](#) was admitted with suspected back pain but showed obvious bilateral forelimb lameness, with right forelimb lameness predominating. Digital pulse amplitudes were increased in the right forelimb, but there was no response to hoof testers. Nonetheless, the horse appeared clinically to have foot pain typical of laminitis. Apparent desensitization of the foot, performed to convince the owner that the horse had foot pain, produced absolutely no change in the lameness. The horse responded rapidly to treatment for laminitis.

3. Inadvertent intrasynovial injection may result in misleading results. For example, accidental injection into the tarsal sheath when attempting to deposit local anesthetic solution around the plantar metatarsal nerves distal to the hock may result in proximal suspensory lesions being missed.
4. Failure to allow sufficient time for local anesthetic solution to be effective may result in a false-negative response in some circumstances. Premature assessment of the response to intraarticular analgesia of the femorotibial joints may result in a false-negative result in association with a cruciate ligament injury. These ligaments have an extrasynovial location, and it may take up to an hour after injection for cruciate ligament pain to be clinically significantly improved.
5. Subchondral bone pain in the condyles of the third metacarpal (metatarsal) bones, associated with extensive sclerosis, in young Thoroughbred and Standardbred racehorses is difficult to abolish in some horses,

Fig. 12-1 • **A**, Lateral and **B**, solar scintigraphic images of the front feet of a horse with suspected back pain but clinical signs of laminitis. There is reduced radiopharmaceutical uptake in the toe region (*arrowheads*). The horse showed no improvement in lameness after apparent desensitization of the lamer right front foot by palmar (abaxial sesamoid) nerve blocks, despite the firm focal pressure applied with artery forceps around the coronary band. However, the horse responded well to symptomatic treatment for laminitis.

and responses to distal limb nerve blocks may add confusion.¹ There may be no localizing clinical signs suggestive of fetlock region pain. Improvement in lameness is sometimes seen after either palmar digital or palmar (abaxial sesamoid) nerve blocks; a “low four-point block” may further improve but not abolish lameness. The horse may be sound only after addition of a subcarpal block of the palmar metacarpal nerves. However, there may negligible response to intraarticular analgesia of the fetlock joint.

Failure to allow sufficient time may in some circumstances result in a false-positive response and then confusion. The tibial and fibular nerves are relatively large, and it takes time for the local anesthetic solution to diffuse into them and to take effect. This time requirement, combined with the deep location of the deep fibular nerve and thus difficulty in precisely locating the site for injection, may result in a response delayed for up to an hour after injection. Testing the efficacy of these blocks through evaluation of cutaneous sensation is unreliable. If the response is deemed to be negative after 30 minutes, and intraarticular analgesia of the compartments of the stifle is then performed and the lameness improves, it may be wrongly inferred that pain originated in the stifle. However, the improvement in lameness may reflect alleviation of pain arising from the hock region. Much wasted time and money may then be spent trying to establish a cause of stifle pain.

Blocking each compartment of the stifle joint separately (e.g., the medial femorotibial joint) may not result in substantial clinical improvement in the lameness, despite the presence of stifle pain. A considerably better response is frequently seen after blocking the medial and lateral femorotibial joints and the femoropatellar joint in combination.

The importance of the clinical examination and repeated observations of a horse cannot be overemphasized. Each clinician has to learn how much to trust nerve blocks. This depends on experience and the frequency of performing blocks. An inexperienced clinician is far more likely to encounter false-negative responses. The results of nerve blocks must be compared with the clinical signs, and if the interpretation is doubtful, the block should be repeated or the area desensitized with a different technique. The clinician must develop experience in the interpretation of improvement in lameness compared with complete alleviation of pain and lameness. This contrast depends to some extent on the degree of the baseline lameness and whether the forelimbs or hindlimbs are involved.

Failure to Perform the Appropriate Nerve Blocks

Failure to perform nerve blocks in a logical and complete sequence can lead to confusion. If the response to a low six-point block in a hindlimb is negative and is followed by a positive response to tibial and fibular nerve blocks, the clinician may conclude that pain arose from the hock. Lesions of the proximal aspect of the suspensory ligament (SL) may be completely overlooked.

Blocking the Wrong Limb

Failure to appreciate that a head nod reflects hindlimb lameness and is not always a sign of forelimb lameness may result in a blocking a forelimb with negative results, when the primary source of pain is in the ipsilateral hindlimb.

Sources of Pain That Cannot Be Desensitized by Nerve Blocks

Many regions of the limbs proximal to the carpus and tarsus cannot be satisfactorily desensitized. In young horses, stress fractures are now well-recognized causes of lameness that pain from which in many circumstances cannot be blocked out. In young or older horses, fractures of the deltoid tuberosity of the humerus (Figure 12-2), the proximal aspect of the fibula (Figure 12-3), the third trochanter of the femur,

Fig. 12-2 • Lateral scintigraphic image of the shoulder region of a 6-year-old Warmblood with acute onset of moderate left forelimb lameness. Note the marked focal increased radiopharmaceutical uptake in the region of the deltoid tuberosity of the humerus. There was a slightly displaced fracture of the deltoid tuberosity of the humerus, which healed satisfactorily with conservative management.

Fig. 12-3 • Caudocranial radiographic image of the left stifle of a general purpose riding horse with recent-onset, episodic, and transient severe left hindlimb lameness. There is a fracture of the proximal aspect of the fibula (*large arrow*). The lucent line separating the different centers of ossification further distally (*small arrow*) should not be confused as a fracture. There was little evidence of bony union after 6 weeks, but after 12 weeks the fracture healed satisfactorily.

Fig. 12-4 • A, Dorsal oblique and **B**, caudal scintigraphic images of the tubera ischii of an 8-year-old Grand Prix show jumper with loss of hindlimb power and a tendency to jump to the right. There is increased radiopharmaceutical uptake in the right tuber ischium and a change of contour compatible with a fracture.

and the tuber ischium (Figure 12-4) are all causes of lameness that are unaffected by nerve blocks.

Muscle injuries, such as tearing or fibrosis of brachiocephalicus or the pectoral muscles, may have no localizing signs (see page 152). Associated lameness cannot be influenced by nerve blocks. Atypical equine rhabdomyolysis can cause hindlimb lameness without any other clinical signs typical of tying up.

Periarticular lesions of the otifle such as collateral ligament injury are usually associated with detectable soft tissue swelling, but injuries of the patellar ligaments can occur with no localizing clinical signs, and associated pain is often unresponsive to intraarticular analgesia (see Chapter 46). I have also examined five horses with acute onset of severe lameness and mild swelling on the cranio-medial aspect of the femoropatellar joint resulting in loss of palpable definition of the patellar ligaments. Lameness was characterized by a markedly shortened cranial phase of the stride at the walk, but less severe lameness at the trot. Ultrasonographic examination revealed the presence of a periarticular hematoma surrounding the patellar ligaments, which themselves were structurally normal.

Pain Associated with a Neuroma

A neuroma may develop secondary to external trauma to a nerve, after abnormal stretching of a nerve, or subsequent to surgery. There is usually intense focal pain on pressure applied directly over the neuroma. However, perineural analgesia of the area may fail to abolish or improve associated lameness. A much better response may be achieved by infiltration of local anesthetic solution directly around the neuroma.

POTENTIALLY CONFUSING RESPONSES TO LOCAL ANALGESIC TECHNIQUES

Improvement without complete alleviation of lameness after perineural analgesia is not always easy to interpret. It may reflect failure to completely alleviate pain from a

single source, or there may be additional sources of pain. Sometimes lameness improves with each successive block (e.g., palmar digital, palmar [abaxial sesamoid], low four-point, and subcarpal nerve blocks). However, the lameness is not associated with any detectable radiological, ultrasonographic, or scintigraphic abnormalities. Sometimes additional useful information can be obtained by performing intraarticular analgesia of the interphalangeal and metacarpophalangeal joints, but if the response is negative the diagnosis remains inconclusive.

Isolation of pain to a region but failure to define the cause is particularly frustrating. For example, intraarticular analgesia of the femorotibial joints may be positive, but no radiological or ultrasonographic abnormalities may be detectable. Nuclear scintigraphy may reveal a generalized increased uptake of the radiopharmaceutical in the distal aspect of the femur and proximal aspect of the tibia compared with the contralateral limb. Medication of the joints may result in no improvement. Exploratory arthroscopy may reveal minor findings (e.g., mild fibrillation of the cranial meniscal ligaments) of questionable relevance, but evaluation of all the joint surfaces and meniscal cartilages is impossible. The definitive diagnosis for the cause of pain remains elusive. Computed tomography (CT) and magnetic resonance imaging (MRI) may permit the identification of subchondral bone injuries and meniscal and ligamentous injuries not accessible to arthroscopic inspection.

The importance of subchondral bone pain as a cause of lameness must not be overlooked. Such pain frequently is present without associated radiological change. A comparison of the responses to intraarticular analgesia and perineural analgesia (and the response or lack thereof to intraarticular medication) may be helpful. With subchondral pain, intraarticular analgesia may have a limited effect. Nuclear scintigraphy is a sensitive indicator of increased modeling in the subchondral bone. MRI has the potential to show subtle structural changes in the subchondral bone.

Until recently, soft tissue lesions within the hoof capsule have proved elusive to definitive diagnosis. Diagnostic

ultrasonography, although possible, has marked limitations. Pool-phase scintigraphic images sometimes are helpful. Examination of the navicular bursa may yield useful information about the bursa, the deep digital flexor tendon, and the distal sesamoidean impar ligament. Advanced imaging techniques such as CT and particularly MRI have the best potential to demonstrate soft tissue pathological conditions, although determining the clinical significance of lesions is not necessarily easy.

False-positive results may be obtained if the horse is only mildly lame at investigation but has a history of a more obvious lameness. The detectable mild lameness may not necessarily reflect the original cause. Lameness that is induced when a horse is lunged in small circles on a concrete surface may not reflect the primary cause of lameness. Thus eliminating this lameness by nerve blocks may be misleading. Lameness induced by flexion also may not reflect the principal cause of lameness. Blocking the flexion response does not necessarily identify the primary cause of lameness.

A pony had moderate forelimb lameness that was markedly accentuated by lower limb flexion. The response to flexion was eliminated by either regional or intraarticular analgesia of the fetlock joint. However, the baseline lameness was unchanged and did not respond to any of the nerve blocks that were repeated on several occasions. Surgical removal of a large osseous fragment from the fetlock joint did not improve the lameness.

False Positive Results of Intrasynovial Analgesia

Lameness may be abolished or substantially improved by intraarticular analgesia of the metacarpophalangeal (metatarsophalangeal) joint with no intraarticular pathology. Pain associated with proximal lesions of the cruciate, straight, or oblique sesamoidean ligaments or the insertions of the suspensory branches may be substantially improved by intraarticular analgesia of the fetlock. Therefore in the absence of both clinical signs suggestive of fetlock joint pain (e.g., synovial effusion, joint capsule thickening, pain on manipulation) and radiological abnormalities it is suggested that the distal sesamoidean ligaments and suspensory branches be evaluated ultrasonographically. Intrathecal analgesia of the digital flexor tendon sheath has the potential to remove pain from injured distal sesamoidean ligaments; it may also relieve pain from the deep digital flexor tendon within the hoof capsule. Therefore the distal sesamoidean ligaments should be included in ultrasonographic examination of the palmar soft tissues of the pastern.

Multiple Sources of Pain in a Limb and More than One Lane Limb

Problems can arise in interpretation of nerve blocks in a horse that is lame in more than one limb, especially if there is more than one source of pain in a limb. Perineural blocks usually last for up to 2 to 3 hours unless a long-acting local anesthetic agent, such as bupivacaine, is used. If a horse is lame in several limbs it is usually easiest to start with the lamest limb and block it first. Interpretation becomes difficult if there is a failure to desensitize all the lame limbs simultaneously. If the blocks in one limb are wearing off, then lameness in the least lame limb becomes less apparent. The horse's tolerance for nerve blocks may

also compromise how much can be done. It may be necessary to start again on another occasion using bupivacaine. If simultaneous lameness of the ipsilateral forelimb and hindlimb is suspected, blocking should begin in the hindlimb. In this situation a substantial amount of the head nod probably originates from the hindlimb component. Because elimination of head nod is vital to improvement after blocking, forelimb diagnostic procedures cannot be fairly evaluated.

Very-Low-Grade Lameness

Nerve blocks, especially in hindlimbs, often result in improvement rather than complete alleviation in lameness. Assessing improvement in subtle lameness is nearly impossible. If the horse has a history of more severe lameness previously, delaying further investigation often is worthwhile. The horse should be worked to accentuate the lameness and simplify interpretation of the response to diagnostic analgesic techniques.

Improvement of Lameness in Some Situations, but Unrelieved Lameness under All Situations:

Which Is the Baseline Lameness?

Sometimes a horse has lameness that appears different in nature under different circumstances. Such findings may be related to more than one cause of lameness, and it is important to recognize this fact. For example, a dressage horse had left forelimb lameness that was apparent to the rider only when the horse was ridden on the right rein (to the right). Clinical examination revealed left forelimb lameness on the right rein on the lunge on a hard surface. This was alleviated by desensitization of the foot. However, desensitization did not alter the lameness that was apparent when the horse was ridden. The cause of the lameness could not be identified. It is vitally important to relate the results of the investigation to the history.

CHALLENGES TO LAMENESS DIAGNOSIS

Very Intermittent or Sporadic Lameness

Sometimes lameness is intermittent, and the horse may be perfectly normal between episodes. Lameness may be provoked only by maximal exercise in competition. It is very important to carefully assess the history and get the owner to pay great attention to any clinical features of the lameness when present. For example, mild, transient diffuse swelling in the midmetacarpal region medially may reflect axial impingement of a splint on the SL (Figure 12-5) (see Chapter 72). Spontaneous resolution of hindlimb lameness after standing still is suggestive of aortoiliacofemoral thrombosis (see Chapter 50). Ask the owner to assess the reaction to manipulation of specific joints when the horse is lame. Pain on manipulation may suggest a joint problem such as hemarthrosis.

If it is not possible to examine the horse when it is lame, nuclear scintigraphic examination can be helpful but also has the potential to mislead (see page 153). For example, an Arab endurance horse had episodic right forelimb lameness that was present only immediately after rides longer than 30 miles. Comprehensive clinical evaluation revealed no evidence of lameness and no suggestions of the cause of previous lameness. Scintigraphic examination

Fig. 12-5 • Transverse ultrasonographic image of the palmar metacarpal soft tissues of the right forelimb of an endurance horse at 10 cm distal to the accessory carpal bone. Medial is to the left. The horse had low-grade lameness at the end of endurance rides that resolved completely within 24 hours. Note the echogenic tissue (*arrowhead*) next to the suspensory ligament (SL). This was a granulomatous reaction between an exostosis on the second metacarpal bone (McII) and the SL. The distal half of the McII was excised and the granulomatous tissue removed. The horse made a complete recovery.

revealed increased radiopharmaceutical uptake (IRU) in the third carpal bone of the lame limb (*Figure 12-6*). Radiographic examination revealed marked increased radiopacity ("sclerosis") of the third carpal bone in the lame limb only, an unusual finding in an endurance horse and thought likely to be of clinical significance. Another Arab endurance horse had an acute-onset, severe right hindlimb lameness that resolved within 48 hours, but mild, extremely transient, and episodic lameness persisted over the next 3 weeks. Clinical evaluation revealed no suggestion of the cause and no current lameness. Nuclear scintigraphic examination revealed focal intense IRU in the medial plantar process of the distal phalanx, and radiographic examination confirmed a recent fracture (*Figure 12-7*).

Lameness associated with a distal caudal radial exostosis may be severe but extremely sporadic and often resolves rapidly. There may or may not be detectable distention of the carpal sheath at the time of lameness. With such a history of episodic severe lameness, it is worthwhile to examine the carpal sheath ultrasonographically, paying particular attention to the contour of the caudal distal aspect of the radius and the architecture of the deep digital flexor tendon (see page 162).

If nuclear scintigraphic and ultrasonographic findings are negative, it is necessary to try to recreate the circumstances under which the horse exhibits lameness. For example, hemarthrosis can cause a very severe but extremely transient lameness. The horse may be completely normal between episodes. Although hemarthrosis is unusual to rare, the joints most likely affected are the

Fig. 12-6 • **A**, Dorsal scintigraphic image of the carpi of an endurance horse with episodic lameness that occurred only during endurance rides. The right forelimb is on the left. There is a focal increased radiopharmaceutical uptake in the middle of the distal row of carpal bones in the right forelimb. **B**, Lateral scintigraphic image of the right carpus. There is increased radiopharmaceutical uptake in the dorsal aspect of the third carpal bone. **C**, Dorsoproximal-dorsodistal oblique radiographic image of the right carpus showing marked increased radiopacity of the radial facet of the third metacarpal bone.

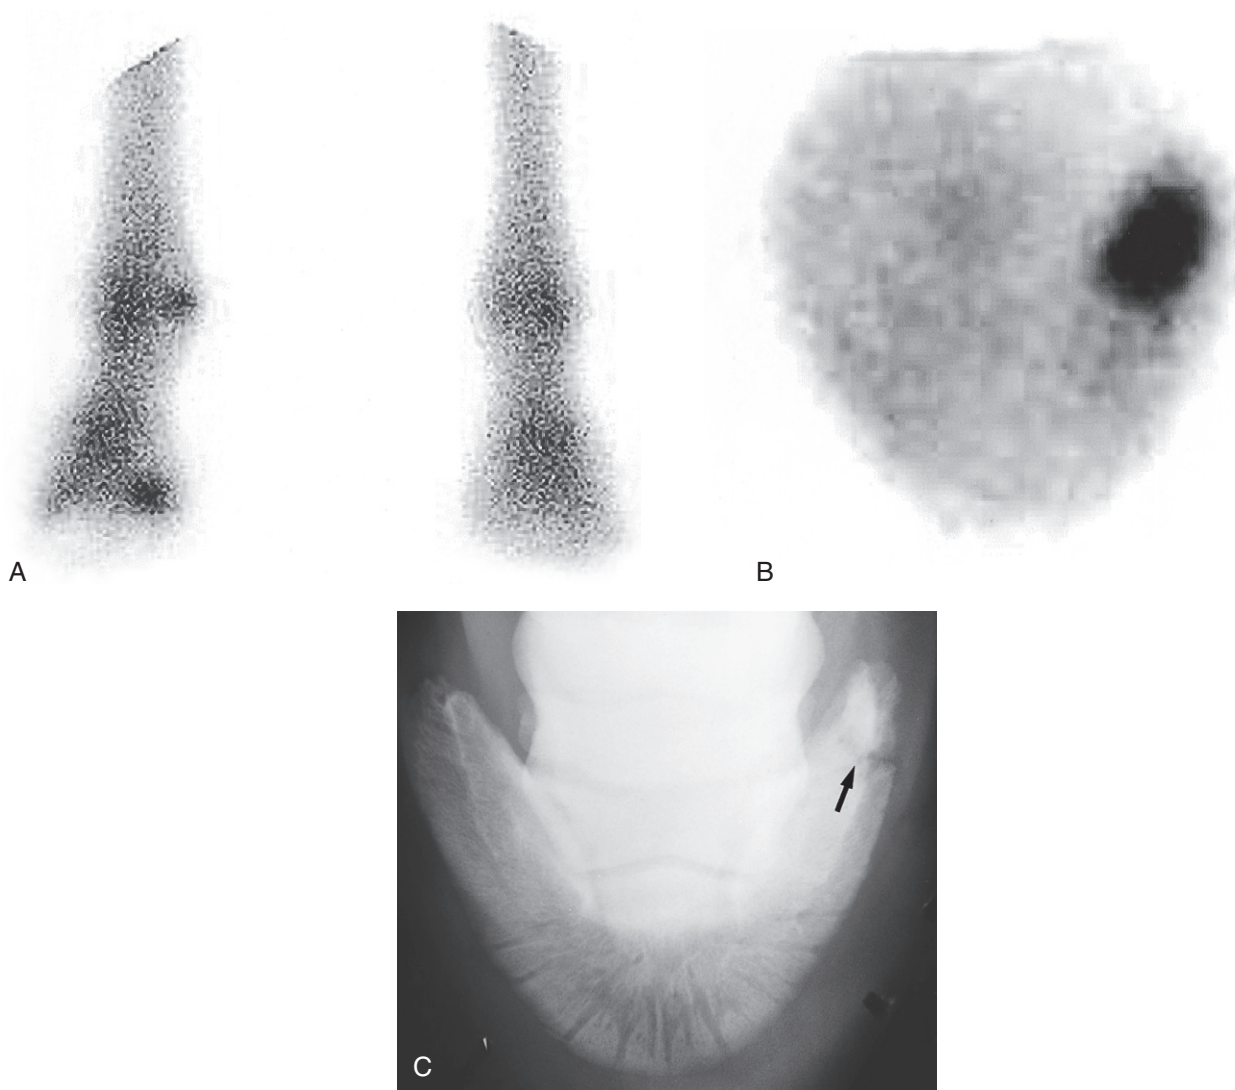

Fig. 12-7 • **A**, Plantar scintigraphic image of the hind feet of an endurance horse with recent onset of left hindlimb lameness that was apparent only after an endurance ride. The horse appeared clinically normal at the time of the examination. There is moderate focal increased radiopharmaceutical uptake in the medial aspect of the left hind foot (*left*). **B**, Solar scintigraphic image of the left hind foot. Medial is to the right. There is markedly increased radiopharmaceutical uptake in the medial plantar process of the distal phalanx. **C**, Plantarodorsal radiographic image of the left hind foot. There is a fracture of the medial plantar process (*arrow*). The horse was treated conservatively and made a complete recovery.

antebrachiocondylar and tarsocrural joints. Diagnosis can be reached only by arthrocentesis at the time of an acute episode, when there is usually some degree of joint capsule distention and pain on manipulation of the affected joint. Working the horse on a treadmill sometimes is helpful (see Chapter 98).

Lameness That Varies within and between Examinations

Sometimes lameness varies considerably in degree both within an examination period and between examinations. This variation makes interpretation of the response to nerve blocks potentially difficult, unless the veterinarian is aware of the fluctuation. It is important to watch a horse move for a sufficient length of time to appreciate any spontaneous changes in the degree of lameness. Horses with a subchondral bone cyst in either the distal aspect of the scapula

or the medial femoral condyle may behave in this way. Within a single examination period the horse may appear sound or lame. In such circumstances it is vital to compare the response to nerve blocks with the clinical signs exhibited. For example, if the characteristics of the lameness are suggestive of shoulder pain, but the lameness is apparently improved after desensitization of the foot, consider the possibility of spontaneous improvement in the lameness that is unrelated to the nerve block. This is, however, an unusual clinical situation, and generally it is best to rely on the results of the diagnostic blocks. A combination of nerve blocks, scintigraphic examination, and radiographic examination may enable a conclusive diagnosis to be reached. Any concurrent clinical signs must not be ignored, even if the owner thinks that swelling may have predated the onset of lameness. Core lesions in the deep digital flexor tendon within the digital flexor tendon sheath may cause

episodic hindlimb lameness that may be difficult to reproduce. Presence of distention of the digital flexor tendon sheath should prompt ultrasonographic evaluation.

The Dangerous Horse and Nerve Blocks

Some horses do not tolerate needle placement and cannot be restrained safely. Nuclear scintigraphic examination sometimes indicates a diagnosis, but the results may be negative. Under such circumstances the horse can be sedated for each block. This approach obviously is time-consuming and may be of low specificity, because time must be allowed for the sedative to wear off adequately before the response to the block can be assessed. During this time the local anesthetic solution has the potential to diffuse away from the site of injection and influence more remote pain. Sedation may result in a rather sloppy gait, which can hinder interpretation, especially with mild hindlimb lameness characterized only by a toe drag. Therefore horse selection is important. However, bearing in mind these limitations, it may be the only way to proceed. Xylazine is the shortest-acting α_2 -agonist available and is the drug of choice, but with a difficult horse, combination with an opioid such as butorphanol is usually necessary.

NEGATIVE RESPONSES

Negative Response to All Nerve Blocks: Where Next?

Occasionally a horse is evaluated for forelimb or hindlimb lameness that is not influenced by any local analgesic technique. Clinical signs may be suggestive of a source of pain (e.g., the foot). The reason for failure to eliminate or improve pain by nerve blocks that should result in desensitization of a region is not understood, but such results do occur occasionally.² If the results of the clinical examination suggest foot pain, the foot should be examined radiographically. Alternatively, there may be no clinical clues for the source of pain. Nuclear scintigraphic examination may be helpful in either situation if the pain is bony in origin but is likely to be less helpful for soft tissue injuries.

Negative Responses to Nerve Blocks, No Clinical Clues, and Negative Scintigraphic Findings

In horses with negative or equivocal scintigraphic findings consideration may be given to systematic radiographic examination, bearing in mind that not all bony lesions are sufficiently active to yield positive scintigraphic findings. However, comprehensive radiographic examination is time-consuming, expensive, and frequently unrewarding and potentially results in unnecessary exposure to radiation. Thus it is usually discouraged. In the forelimb, unusual causes of lameness such as neurological disease (usually lower motor neuron diseases, such as equine protozoal myelitis), cervical nerve root pain (radiculitis), spondylosis of the cranial thoracic vertebrae, and pectoral, sternal, or rib pain may be considered. Pain associated with advanced osteoarthritis of the scapulohumeral joint or lesions of the tendon of the biceps brachii is not reliably abolished by intraarticular analgesia of the scapulohumeral joint or intrathecal analgesia of the intertubercular bursa, respectively. Therefore radiographic examination of the cervical and cranial thoracic vertebrae, the scapulohumeral joint, and the cranial ribs may be justified, together with

ultrasonographic examination of the shoulder region. In the hindlimb, neurological disease and thoracolumbar or pelvic soft tissue injuries visible neither on pool nor bone phase scintigraphic images should be considered. Keep in mind that horses with forelimb or hindlimb lameness could potentially have a distant source of pain, and comprehensive imaging (whole body bone scan, for instance) may be necessary.

NECK LESIONS AND FORELIMB LAMENESS

Forelimb lameness that is unassociated with primary limb pain has been recognized in association with bony lesions of the midcervical and caudal cervical vertebrae and the cranial thoracic vertebrae (see Chapters 52 and 53).^{2,3} There are not necessarily any detectable clinical signs that can be related to the neck. In horses with confusing forelimb lameness, evaluation of the neck with radiography, scintigraphy, or both modalities is certainly indicated.

REFERRED PAIN

The concept of referred pain is well recognized in people but is more difficult in the horse. We must accept that referred pain originating from a lesion far removed from the lame limb may contribute to pain and thus cause lameness.

PREVIOUSLY UNRECOGNIZED CAUSES OF LAMENESS PROXIMAL TO THE CARPUS AND TARSUS

I think it is naive to consider that all potential causes of lameness proximal to the tarsus and carpus have been recognized. Injuries that primarily involve bone usually can be identified with nuclear scintigraphic examination. However, scintigraphy is rather insensitive in the identification of soft tissue injuries, although it may help identify some muscle injuries (Figure 12-8). Muscles can be examined ultrasonographically, but we need to know where to look for damage. Acupuncture trigger point sensitivity may provide information. Use of muscle stimulators may help to identify superficial muscles that are damaged. We know that the horse can tear the fibularis tertius, resulting in pathognomonic clinical signs. We do not know if minor injuries to this modified muscle could cause lameness. Tendonous and ligamentous pain without palpable abnormalities and therefore without a specific indication for ultrasonographic examination must always be considered. We must remain open-minded and search for other means of diagnosis.

MISINTERPRETED IMAGING FINDINGS THAT RESULT IN MISDIAGNOSIS

In horses in which the results of local analgesic techniques are equivocal or negative, it may be tempting to rely on the results of other diagnostic techniques, such as radiography, ultrasonography, and nuclear scintigraphy, without necessarily relating them to the initial clinical signs. Although these imaging modalities may help to confirm a

Fig. 12-8 • Lateral scintigraphic image of the right elbow region of a 4-year-old Warmblood stallion with right forelimb lameness evident only at the walk, which was unaltered by any local analgesic technique. Radiopharmaceutical uptake was increased in the biceps brachii muscle (*arrow*), which corresponded to an area of increased echogenicity compatible with fibrosis.

Fig. 12-9 • Lateral scintigraphic image of the tarsus of a 7-year-old riding horse. Note the marked focal increased radiopharmaceutical uptake in the hock. Lameness was completely alleviated by desensitization of the fetlock region. There was no radiological abnormality of the hock.

clinical diagnosis, they also have the potential to mislead, especially if interpreted in isolation.

The horse illustrated in [Figure 12-9](#), with focal IRU in the hock, was admitted with left hindlimb lameness that was alleviated by desensitization of the fetlock region. The

Fig. 12-10 • Lateral scintigraphic image of the tarsus and tibia of a 12-year-old advanced event horse with bilateral forelimb lameness associated with distal interphalangeal joint synovitis. The horse had no history or evidence of hindlimb lameness and competed successfully thereafter. Note the intense increased radiopharmaceutical uptake in the tibia. The horse was reexamined approximately 8 months later with similar results. The horse had been competing successfully but had recurrent forelimb lameness.

Fig. 12-11 • Solar scintigraphic image of the right front foot of a 6-year-old Warmblood. There is increased radiopharmaceutical uptake in the region of insertion of the deep digital flexor tendon on the distal phalanx. The gait characteristics were typical of proximal limb lameness, and lameness was unaltered by desensitization of the foot. The horse had a fracture of the deltoid tuberosity of the humerus.

horse illustrated in [Figure 12-10](#), which has IRU in the distal tibia, was admitted with forelimb lameness. No hindlimb lameness was observed at any time, even after alleviation of the forelimb lameness. The horse in [Figure 12-11](#), with IRU in the region of insertion of the deep

Fig. 12-12 • A, Flexed dorsolateral-palmaromedial oblique radiographic image of the right front proximal interphalangeal (PIP) joint of a 14-year-old advanced event horse with acute onset lameness, which was worst on the left rein on hard or soft surfaces. Lameness was improved by palmar digital analgesia and abolished by palmar (abaxial sesamoid) nerve blocks. There was no response to intraarticular analgesia of the PIP or distal interphalangeal (DIP) joints. There is extensive periarticular modeling of the dorsoproximal aspect of the middle phalanx (*arrowhead*), effectively increasing the effective PIP joint surface area. There is also mild enthesophyte formation at the insertion of the oblique sesamoidean ligaments on the proximal phalanx (*arrow*). **B,** Longitudinal ultrasonographic image of the pastern of the same horse as **A**. Proximal is to the left. There is enthesophyte formation at the insertion of the oblique sesamoidean ligaments (*arrow*), which appeared structurally normal. This is another coincidental finding but is an observation commonly made in conjunction with dorsal extension of the PIP joint. **C,** Transverse ultrasonographic image of the medial aspect of the coronary band of the same horse as **A** and **B**. There was subtle soft tissue swelling palpable dorsomedially. The medial collateral ligament of the DIP joint is diffusely mildly hypoechoic, especially dorsally, but is not enlarged, and there is considerable periligamentous hypoechoic fluid. The skin surface is abnormally convex. Diagnosis: acute desmitis of the medial collateral ligament of the DIP joint.

digital flexor tendon, had lameness associated with a fracture of the deltoid tuberosity of the humerus.

Not all radiological abnormalities are of clinical significance. Extensive periarticular modeling is sometimes seen on the dorsal aspect of the proximal interphalangeal joint, effectively increasing the joint surface area, probably to increase stability (Figure 12-12). These radiological abnormalities are not necessarily associated with intraarticular

pathology or pain. The horse in Figure 12-12 had lameness improved by palmar digital analgesia and abolished by palmar (abaxial sesamoid) nerve blocks. Lameness was not altered by intraarticular analgesia of the proximal interphalangeal joint. Right forelimb lameness, which was worst on the right rein on a circle, was caused by an acute injury of the medial collateral ligament of the distal interphalangeal joint.

ODD LAMENESS APPARENT ONLY DURING RIDING

Some causes of lameness are apparent only when the horse is ridden. Some of these are easy to block, but a minority fail to respond to local analgesic techniques. Consideration must always be given to rider-induced lameness (see page 157 and Chapter 97), discomfort caused by tack, and gait abnormalities arising through thoracolumbar (see Chapter 52), sacral, and sacroiliac pain (see Chapters 50 and 51). The possibility of the rider's weight compressing muscles in the saddle and caudal neck region and nerve compression should be considered as potential causes of forelimb pain.

Stepping short on one forelimb at the walk, a feature that may be more easy to feel than to see, is a characteristic of pain in the ipsilateral brachiocephalicus muscle. Palpation of the muscle is usually strongly resented. Lameness may be inapparent at the trot. Horses respond well to physiotherapy treatment.

Lesions of the tendon of the biceps brachii within the intertubercular bursa may result in lameness at the walk characterized by a variable degree of shortening of the cranial phase of the stride; however, at the trot lameness may be absent or slight.

Stepping short on one hindlimb at the walk but having no detectable lameness at the trot is a poorly understood syndrome that may be sudden in onset and tends to be persistent, despite prolonged rest, with or without physiotherapy, osteopathy, chiropractic manipulation, or acupuncture treatment. Such horses usually are worst when ridden at the walk but perform well at all other gaits. There is no response to antiinflammatory analgesic drugs or any analgesic technique. Comprehensive radiographic, scintigraphic, and ultrasonographic examinations are unrewarding.

There is a syndrome of forelimb lameness that is apparent only when a horse is ridden (bareback or with a saddle), which at worst often appears as a hopping-type gait, often most severe with the lame limb on the outside of a circle. Affected horses may try to break to canter in preference to trotting. This lameness is not responsive to any analgesic technique, and radiographic, ultrasonographic, and scintigraphic examination of the forelimbs, neck, ribs, sternum, and thoracolumbar region usually results in no detectable abnormality. There is a poor response to prolonged rest, with or without physiotherapy, osteopathy, chiropractic manipulation, or acupuncture treatment. There is no response to nonsteroidal antiinflammatory medication. A potential possible cause may be muscle or nerve injury axial to the scapula.

IDENTIFIABLE LESIONS: WHICH CONTRIBUTE TO THE CURRENT LAMENESS?

The presence of radiological lesions is not necessarily synonymous with pain, or the pain may be low grade and not compromise the horse's gait sufficiently to be recognized by the rider. For example, a horse may have an acute lameness referable to the stifle. Several lesions may be identified radiologically (e.g., smooth flattening of the middle of the lateral trochlear ridge of the femur, modeling of the medial articular margin of the tibial plateau, and a complete fracture of

the proximal aspect of the fibula [see Figure 12-3]). It is likely that acute lameness is related to the fibular fracture. The horse in Figure 12-3 had been coping despite radiological evidence of both osteochondrosis of the femoropatellar joint and osteoarthritis of the medial femorotibial joint.

OTHER CAUSES OF LAMENESS

Lacerations and Occult Spiral Fractures

Acute-onset, moderate-to-severe lameness sometimes develops within 2 to 3 weeks of trauma to, or laceration over, a long bone (see Figures 3-3 and 3-4). Sometimes lameness is first observed when the horse is still restricted to box rest and controlled exercise while the wound heals. There may or may not be any detectable focus of pain. Consideration must always be given to the possibility of an occult spiral fracture of, for instance, the radius that was obviously sustained at the time of the initial injury. Occult spiral fractures are most common in the radius but can involve the third metacarpal or metatarsal bones and tibia. Radiographic examination should be performed to eliminate this possibility.

Rib Lesions

A fracture of one or more cranial ribs is a rather unusual cause of forelimb lameness that usually is a sequel to direct trauma, such as a collision with another horse or a gate post, or a fall. There are usually no localizing clinical signs, although secondary neurogenic muscle atrophy may develop within the next 10 to 14 days. The lameness may suggest an upper limb problem. Diagnosis is dependent on radiographic, ultrasonographic, or scintigraphic identification of the fracture.

Sternal Injury

Sternal injury usually causes a change in behavior, such as a tendency to buck when first tacked up and mounted (i.e., extreme cold back behavior) rather than lameness. Frequently it is not possible to elicit pain by deep palpation.

Fracture of the Summits of the Dorsal Spinous Processes in the Withers Region

Acute fractures of the withers usually result in a very shortened forelimb stride and a tendency to move very closely in front ("the miniskirt walk"). There is usually obvious palpable deformity of the withers region. Diagnosis is confirmed radiologically.

Temporomandibular Joint Pain

Pain associated with one or both temporomandibular joints may cause reluctance for the horse to take the bit properly, crookedness in the head and neck carriage, and secondary gait irregularities. The joints can be assessed by applying firm pressure over each joint, which may cause pain, and by opening the mouth and moving the upper and lower jaws relative to one another and assessing mobility. Thermography may be a sensitive indicator of local inflammation. If temporomandibular pain is suspected, further investigation can be performed using nuclear scintigraphic examination and diagnostic ultrasonography.⁴ Radiography is relatively insensitive unless major bony changes are present.⁵ The use of a rostral 35-degree lateral 40-degree ventral-caudodorsal oblique view is recommended.⁶

Neurological Problems and Lameness or Stiffness

Early compressive lesions of the cervical spinal cord can cause an apparent low-grade hindlimb lameness that is characterized by slight toe drag and asymmetrical movement of the hindquarters. Signs of weakness or ataxia may not be evident unless a comprehensive neurological examination is performed, especially if the horse is quite fit and fresh. Neurological signs may be seen only when the horse is tired and not compensating for its gait deficits.

Equine protozoal myelitis can cause rather bizarre forelimb or hindlimb gait abnormalities, either unilaterally or bilaterally. It should be considered in the differential diagnosis of odd gait abnormalities in horses that reside or have spent time in North America (see Chapter 11).

Damage to the branch of the radial nerve that results in an innervation of the extensor muscles of the carpus and digits may cause a subtle gait abnormality that is characterized by a tendency to stumble and is associated with slight knuckling of the carpus and distal limb joints.

Stiff horse syndrome⁷⁻⁹ and equine motor neuron disease¹⁰ are unusual neurological conditions in which the horse moves better in the trot and canter than at a walk and may stand abnormally.

Shivering behavior often is seen in one or both hindlimbs in association with hindlimb lameness. The two conditions generally are unrelated. Shivering behavior may be more apparent when the horse is stressed. The behavior can make it difficult to assess whether any manipulation of the limb causes pain, or whether the horse is uncomfortable with one hindlimb picked up.

Stringhalt, or exaggerated flexion of a limb, usually a hindlimb, results in a gait abnormality most obvious at the slower speeds of walk and trot. It is not usually directly associated with any other form of lameness. It may be sudden or insidious in onset.

Congenital abnormalities of the first ribs in association with abnormalities of the adjacent brachial plexus have been seen as a cause of persistent forelimb lameness (Figure 12-13).

Acute-onset, severe, and persistent forelimb lameness has been seen in association with a mediastinal abscess that encroached on the nerve roots of the seventh cervical and first thoracic vertebrae, the stellate ganglion, and the first rib (Figure 12-14). Measurement of fibrinogen may help to identify the presence of an infective or inflammatory process.

Lyme Disease

Lyme disease has frequently been incriminated as a cause of shifting lameness that involves several limbs, but confirmed cases are extremely rare.¹¹ Many horses that are in areas where there are many ticks have relatively high antibody titers to *Borrelia burgdorferi*,^{11,12} but this is not diagnostic of clinical disease. Lyme disease may be suspected in adult horses in endemic areas when unusual synovitis develops in absence of any known injection history or presence of a wound (see Chapter 66).

Immune-Mediated Polysynovitis

Immune-mediated polysynovitis is relatively uncommon but may result in generalized stiffness associated with transient synovial distention of several joint capsules. It is frequently not possible to identify the underlying cause,

Fig. 12-13 • Postmortem specimen showing an anomalous first rib from a 3-year-old Thoroughbred with right forelimb lameness that was not altered by any local analgesic technique. There was an abnormal web of fibrous tissue that extended from this anomalous rib to incorporate part of the brachial plexus on the right side.

Fig. 12-14 • A 7-year-old pony with severe right forelimb lameness that progressively deteriorated. The pony had an increased fibrinogen level and intermittent pyrexia. There was a mediastinal abscess that encroached on the roots of the seventh cervical and first thoracic nerves, the stellate ganglion, and the first rib.

but this condition usually responds to corticosteroid medication (see Chapter 66).

Tack-Induced Pain

An ill-fitting saddle can induce back pain and restricted action or poor performance. The bit can induce pain

through poor fit (too narrow or too wide), being too low in the horse's mouth, banging on the canine teeth, pinching the corners of the horse's mouth, or being too severe. Any oral pain related to the bit, sharp teeth, or lacerations of the tongue, cheeks, or corners of the horse's mouth may cause reluctance to accept the bit properly and gait irregularities.

Rider-Induced Problems

The rider has a potentially huge influence on the gait of the horse. If a horse is not going forward properly, either because the rider is restricting it or because the rider is not asking it to go forward properly, the forelimb and hindlimb gaits may appear irregular, mimicking pain-induced lameness. An overweight rider who is too heavy for the horse may induce hindlimb lameness. A rider who constantly sits crookedly may induce back pain and hindlimb lameness. (Rider-related problems are discussed further in Chapter 97.)

Physical Limitations of the Horse, Temperament, and Confidence

With appropriate handling and training, most horses are cooperative. However, a previously compliant horse can very rapidly change if regularly handled and ridden by someone who lacks confidence, technique, or strength. Such a horse can quickly develop evasions, such as not going forward properly, rearing, bucking, or taking off. These problems may be, but are not necessarily, pain-related. A horse that has never been trained properly may be very difficult and even potentially dangerous to the rider. Horses home-bred by amateur enthusiasts are high-risk candidates. Some horses are innately lazy and unwilling to go forward. Others are very exuberant and excessively forward going and "fizzy." The veterinarian may be asked to investigate any of these behavioral features as a potentially pain-related problem.

It is important to establish a horse's previous performance. It may be useful to see a video. Determine if there has been a change in rider or management. Establish what the horse is being fed and how much work it is getting: there is a tendency for people to overfeed and underwork horses. A comprehensive clinical evaluation may need to be repeated on several occasions before you can determine if it is a pain-related problem. Nuclear scintigraphic examination of selected areas may be useful to eliminate the presence of any underlying problems and to convince the owner that there is not a physical problem. A change of rider or work pattern may be necessary. The use of high doses of nonsteroidal, antiinflammatory drugs (e.g., 2 to 3 g of phenylbutazone, twice daily for at least 7 to 10 days) can be helpful to determine if the problem is pain related, but be aware that there may be a placebo effect. Not all pain responds to phenylbutazone, so a negative response does not preclude a pain-induced problem (see Chapter 97).

Reproductive Problems*

Some mares become more difficult to handle and ride when in season. Mares with coliclike discomfort, hindlimb

lameness, or back pain when the rider is in the saddle may have painful ovaries, especially in the periovulatory period.^{13,14} Indeed, pressure applied to the ovaries per rectum can elicit a pain response.¹⁵ Palpation of a large ovulatory follicle or a follicle that has recently ovulated, other genital tract characteristics of estrus, and concomitant behavioral signs of estrus may support this diagnosis. The discomfort should subside shortly after ovulation, but it may recur with future cycles.¹⁴

Periovulatory discomfort is thought to be caused by a combination of extremely enlarged follicles that affect neighboring tissues and the release of follicular fluid during ovulation, some of which may leak into the peritoneal cavity and cause localized inflammation. These factors may result in localized pain that lasts approximately 24 to 48 hours.

The estrous cycle is also characterized by changes in the hormonal profile. Specific balances between gonadotropins and sex steroids are necessary for smooth transitions between phases of the reproductive cycle. It has been proposed that any alteration in the ratios between luteinizing hormone and follicle-stimulating hormone; androgens, estrogens, and progestins; or both results in erratic behavior that leads to poor performance. The judicious use of a synthetic progestagen such as altrenogest (Regumate, Intervet, Millsboro, Delaware) to stop the mare's cycling can sometimes be helpful. Ovariectomy is a treatment of last resort and does not reliably influence performance-related problems. Keep in mind that the mare's behavior when out of season will be the end result if ovariectomy is performed. Some Thoroughbred fillies appear to be predisposed to exertional rhabdomyolysis and have been successfully treated with anabolic steroids such as testosterone and boldenon undecylenate (Equipose).

Although some stallions can be used successfully for both competition and breeding, especially if the management is good and a very clear distinction is made with handling routines, others cannot focus adequately and thus perform athletically below expectations. Performance may be enhanced by castration. However, although malorientation of testicles is frequently blamed for lameness or poor performance, in the Editors' experience this is highly unusual.

A scirrhus cord in a gelding or mastitis in a mare can cause loss of hindlimb action and hindlimb stiffness. Chronic episodic, transient hindlimb lameness associated with strenuous work (jumping) has been seen in a stallion with large internal inguinal rings.¹⁶ The lameness resolved after herniorrhaphy.

Other Medical Problems

Muscle tumors are a rare cause of lameness, but usually there is localized soft tissue swelling, which should prompt ultrasonographic evaluation and muscle biopsy. Gastric ulceration is usually not a cause of overt lameness but may compromise performance, such as causing difficulties in jumping large spread fences.

Atypical Equine Rhabdomyolysis

Occasionally, equine rhabdomyolysis occurs without any of the typical signs of tying up, generally in event horses

*The Editors acknowledge the contribution of J. Jorgensen and R. Mansmann, who contributed a chapter entitled "Estrous Cycle and Performance in Athletic Mares" to the first edition of *Diagnosis and Management of Lameness in the Horse*.

or endurance horses. Most commonly this is recognized during competition, but it can occur at other times. A horse may pull up with an unexplained unilateral or bilateral hindlimb lameness, which may be mild to severe. The horse does not show any distress, and there are no localizing clinical signs. This may resolve, only to recur in association with exercise. Measurement of serum muscle enzymes will reveal elevated creatine kinase and aspartate transaminase concentrations. The relative degree of rise in concentration of the two enzymes will depend on whether this is a single episode or if recurrent, how frequently the horse is experiencing abnormal muscle stress, and the recent work history. Alternatively, a horse may be performing suboptimally, with reduced quality of paces and reduced scope when jumping, sometimes becoming more restricted during a work period. Affected horses may have focal or diffuse, linear regions of IRU in affected muscle groups in bone phase scintigraphic images, sometimes varying in intensity in different muscle groups. Aspartate transaminase concentration will be elevated.

Vascular Lesions

Venous obstruction in the axilla has caused episodic lameness associated with extensive soft tissue swelling in the antebrachium. Diagnosis was confirmed by a vascular scin-

tigraphic study. Brachial thrombosis has also been associated with severe forelimb lameness.¹⁷

Bone Fragility Disorder

A bone fragility disorder of unknown cause has been described in a small number of horses in the western United States.¹⁸ It is characterized by an acute or chronic multilimb lameness, with no localizing clinical signs in some horses. In a small proportion there is bowing of the scapulae, lordosis, or cervical stiffness. The source of pain cannot be identified using diagnostic analgesia. Numerous sites of IRU are identified in the axial skeleton and proximal aspects of the forelimbs and hindlimbs. The condition may be progressive.

Panosteitis-like Lesions

Panosteitis is a well-recognized condition in dogs but has not been documented in the horse. However, I am aware of three horses that have had clinical and radiological signs consistent with this condition. In the dog the cause is unknown, but the relatively high frequency of occurrence in young German shepherd dogs suggests some heritable predisposition. It results in a lameness that waxes and wanes in severity, with episodic severe non-weight-bearing lameness. In the horse this condition has been recognized in mature sport horses and has been characterized by a lameness varying in severity from mild to non-weight

Fig. 12-15 • A, Dorsomedial-palmarolateral oblique radiographic image of the metacarpal region of the left forelimb of a 9-year-old advanced event horse with left forelimb lameness that varied in severity from mild to severe. Perineural analgesia of the palmar and palmar metacarpal nerves in the proximal metacarpal region, performed when lameness was relatively mild, resulted in improvement and the development of right forelimb lameness. There are patchy increases in radiopacity in the medulla of the third metacarpal bone, thickening of trabecula, and endosteal new bone consistent with a panosteitis-like condition. Lesions were associated with multifocal regions of intense increased radiopharmaceutical uptake (IRU). **B,** Lateromedial radiographic image of the left radius of an 8-year-old Thoroughbred event horse with sporadic severe lameness that was unresponsive to local analgesic techniques. Cranial is to the left. Extensive endosteal new bone is present, especially cranially, along with patchy increased opacity in the medulla, consistent with a panosteitis-like condition. Lesions were also present in the right forelimb and were associated with multifocal regions of intense IRU.

bearing, with no localizing clinical signs. The response to perineural analgesia has varied depending on the site of the lesions, which may be multifocal. All three horses had a unilateral or bilateral forelimb lameness, two with the most severe lesions in the radius and one with the most severe lesion in the third metacarpal bone. The lesions are typified radiologically by a patchy increase in medullary

opacity, especially near the nutrient foramen, coarse trabeculation, and endosteal thickening (Figure 12-15). The lesions are associated with moderate to intense IRU. Lesions may be identified in more than one limb, although not all appear to be symptomatic. In the dog the condition is managed by systemic administration of nonsteroidal anti-inflammatory drugs and is usually self-limiting.

Chapter 13

Assessment of Acute-Onset, Severe Lameness

Sue J. Dyson

FIELD DIAGNOSIS OF THE INJURED HORSE

The assessment of an acutely lame horse presents a challenge in diagnosis and in dealing with the people associated with the horse, particularly if lameness occurs at a competition. The horse may have fallen and been lame immediately or may have pulled up lame, and the veterinary surgeon may be called to examine the horse on course in full view of the public.

Ideally the horse should be transported to an examination area for comprehensive evaluation, but the veterinary surgeon must establish whether the injured limb requires support before the horse is moved. Although the horse may be very lame, establishing a definitive diagnosis for the cause of the lameness at this stage may be difficult.

This may surprise riders, trainers, and owners, and maintaining their confidence in what is an emotionally charged situation can be quite difficult. If a fracture is suspected, pressure to destroy the horse humanely without delay may be felt. Although some fractures are catastrophic and merit immediate destruction of the horse on humane grounds (e.g., a spiral fracture of the humerus), other serious fractures can be repaired. Therefore as much information as possible about the site of the fracture and its configuration should be obtained before a decision is made. The limb should be supported appropriately before the horse is moved for radiographic examination. If a horse must be destroyed on humane grounds at a competition, this should be done off the course.

Although a diagnosis may be obvious in some horses immediately after the onset of lameness, the veterinarian must recognize that severe lameness may occur without an evident cause. Serial reexaminations over the following hours or days may be required before a diagnosis can be reached. Sometimes the lameness resolves spontaneously within 12 to 18 hours and its cause is never established.

The clinician must be aware of the most common causes of acute-onset, severe lameness, which include the following:

- Subsolar abscess
- Fracture
- Laminitis
- Intrasynovial sepsis
- Periarticular cellulitis

When lameness occurs during training or competition, a spectrum of other injuries must be considered. However, a history of acute-onset, severe lameness during exercise must not mislead the clinician into thinking that lameness must be caused by internal or external trauma associated with exercise. Lameness may still be caused by pain from a subsolar abscess.

This chapter describes a systematic approach to management of a horse with sudden-onset, severe lameness and focuses particularly on injuries that occur during work.

ASSESSMENT

Medical History

While performing an initial visual appraisal of the horse, establishing a history is useful. The examiner must determine the following:

- Any previous lameness, tendon or ligament injury, or history of tying up.
- Date of last shoeing.
- Circumstances of lameness: whether the horse was performing normally, fell, hit a fixed fence, or collided with a fixed object such as a guide rail or a tree. The horse may have reared in the starting stalls or reared and fallen over backward. Another horse may have kicked it. If the horse fell, could it have fallen into stinging nettles? Stinging nettles may cause both an urticarial reaction and inability to bear weight on the affected limb for several hours.

The clinician should also be aware of common injuries in the discipline in which the horse is competing.

The horse may be distressed because of the severity of pain and excited because of the atmosphere of a competition and thus difficult to restrain and examine adequately. Sedation with romifidine or detomidine, with or without butorphanol, may be necessary to facilitate examination of the horse. A horse with an acute hindlimb muscle tear or hemorrhage may show evidence of pain mimicking signs of colic.

The horse's posture should be observed while it stands still and walks a few steps. If the horse bears weight only on the toe, it may be inapparent that the horse has lost some support of the fetlock because of rupture of the

superficial digital flexor tendon (SDFT) in the metacarpal region or at the musculotendinous junction in the antebrachium, unless it walks a few steps.

Limb Examination

The veterinarian should establish whether the horse is able and willing to bear weight on the limb, bearing in mind that after a fall a neurological component may contribute to the lameness, in addition to the pain. The horse's demeanor should be assessed; the degree of pain and distress usually but not invariably reflects the severity of the injury. The horse may be greatly distressed, shifting weight constantly between limbs, and may be reluctant to move. Reluctance to move may be caused by a bilateral problem (e.g., bilateral severe superficial digital flexor [SDF] tendonitis) or a more generalized problem such as equine rhabdomyolysis (tying up).

The horse should be carefully appraised visually to identify areas of swelling or a laceration. If the horse's limbs are covered in mud or grease (commonly applied to the limbs during the speed and endurance phase of a Three Day Event), this should be washed off before one proceeds with the evaluation. Boots, bandages, and the saddle and martingale should also be removed. Temporary studs in the shoes should be removed because they may be more difficult to remove later if the injury is severe.

The horse may be obviously lame on a hindlimb or forelimb, but this may mask a similar, less severe injury in a contralateral limb or a different injury; therefore all limbs should be assessed carefully. For example, a racehorse may develop a lateral condylar fracture of the third metacarpal bone in one limb and SDF tendonitis in the contralateral limb. Although the former injury results in a more severe lameness, the latter may be more important to the horse's long-term prognosis.

Occasionally, forelimb and hindlimb lameness are concurrent. Each limb should be palpated systemically with the horse bearing weight and not bearing weight. The examiner should pay careful attention to heat, swelling, abnormal muscle texture, pain on firm pressure, pain induced by manipulation of a joint, restriction of flexibility of a joint, an abnormal range of motion of the joint, audible or palpable crepitus, and the intensity of the digital pulse amplitudes.

The position of the shoe should be assessed carefully. A shoe that has moved slightly may result in nail bind. Hoof testers should be systemically applied across the wall and sole, gently at first and then firmly. Percussion should also be applied to the sole of the foot with the limb picked up and to the wall with the limb bearing weight. The clinician should not forget that if the sole is very hard, eliciting pain with hoof testers may not be possible, despite the presence of a subsolar abscess.

The limbs should be carefully assessed for lacerations. Serious damage to underlying structures may have occurred if the laceration was sustained while the horse was moving at speed, and the position of the laceration and the site of damage to underlying structures may not coincide.

Shoulder and Chest

Injuries to the shoulder region usually result from a fall or collision, which may result in severe bruising only or a fracture. A fracture of the supraglenoid tubercle of the scapula

Fig. 13-1 • Mediolateral radiographic image of the left shoulder of an advanced event horse that had fallen during competition 3 days previously and developed severe left forelimb lameness from a displaced comminuted fracture of the supraglenoid tubercle of the scapula.

results in severe lameness (Figure 13-1). Slight soft tissue swelling may develop, usually without audible or palpable crepitus, and pain on palpation may be difficult to differentiate from that caused by severe bruising alone. Articular fractures of the scapula may be associated with audible crepitus on manipulation of the limb. Fractures of the body of the scapula or the humerus are usually associated with severe lameness, soft tissue swelling, and pain in that area.

After collision with a fixed object, or occasionally a fall, the scapulohumeral joint may become luxated or subluxated, with or without a fracture of the glenoid cavity of the scapula. The horse bears weight on the limb reluctantly, soft tissue swelling develops rapidly, and the distal aspect of the scapular spine may become more difficult to palpate. The limb may appear straighter than usual. A collision also may result in collateral instability of the shoulder, so-called *shoulder slip*, usually caused by trauma to nerves of the brachial plexus. The horse may have pain-related lameness because of bruising, together with mechanical lameness caused by neurological dysfunction (Figure 13-2).

Although major fractures of the scapula and humerus are usually readily evident by clinical signs, most other shoulder injuries require radiographic and sometimes ultrasonographic examination for a diagnosis to be reached.

Pectoral muscle tears may result in similar clinical signs, with severe lameness and distress. Repeated clinical examinations may reveal the site of muscle rupture, with increasing evidence of hemorrhage, inflammatory effusion, and edema.

Rib fractures can also result from direct trauma or from falls and occur most commonly in steeplechasers and polo

Fig. 13-2 • Lateral radiographic image of the midcervical region of a 6-year-old event horse that fell on a cross-country course. The horse was not bearing weight on the left forelimb and showed moderate hindlimb ataxia. The synovial facet joints were fractured between the sixth and seventh cervical vertebrae (arrow). A cause of the forelimb lameness was not identified, and the lameness resolved within 24 hours. The horse had a complete functional recovery but had some residual neck stiffness.

Fig. 13-3 • Mediolateral radiographic image of left elbow of an event horse that was very lame after a fall and stood with the elbow dropped. The olecranon of the ulna sustained a displaced, comminuted fracture.

ponies. Fractures in the region of the scapula and triceps result in acute, severe forelimb lameness. More caudal fractures may result in extreme stiffness and may cause severe respiratory embarrassment.

Lameness associated with the upper forelimb may also be caused by strain of the biceps brachii or brachiocephalicus muscles or hematoma formation. Careful, deep palpation of these muscles is required to identify focal pain and possibly swelling or abnormal muscle texture.

Elbow and Carpus

Acute-onset lameness associated with pain arising from the elbow region is rare, except as the result of a fall or kick. Fracture of the olecranon process of the ulna is the most common injury (Figure 13-3). If the fracture is nondisplaced, the horse may stand normally but with severe pain; or if the fracture is complete with loss of triceps function, the horse stands with a dropped elbow.

Acute-onset lameness associated with the carpus occurs most commonly in racehorses, both flat racehorses and steeplechasers, and usually is associated with a chip or slab fracture or less commonly with hemarthrosis. Synovial effusion within the antebrachiocondylar or middle carpal joint usually develops rapidly. The horse may resent maximal flexion of the carpus, and direct palpation of the carpal bones may elicit pain. Fracture of the accessory carpal bone usually results from a fall and occurs most commonly in steeplechasers; such fractures may be associated with effusion within the carpal sheath. Acute tears of the accessory ligament of the SDFT sometimes occur in polo ponies and rarely in trotters, with associated distention of the carpal sheath. Tenosynovitis caused by hemorrhage most often causes acute, severe lameness, but pain can be transient and intermittent.

Forelimb Soft Tissue Injuries

Injuries of the forelimb suspensory ligament (SL) (proximal, midbody, and branch lesions) and of the forelimb SDFT occur most commonly in racehorses and event horses, whereas desmitis of the accessory ligament of the deep digital flexor tendon (ALDDFT) occurs more commonly in show jumpers, older steeplechasers, and polo ponies.

Severe, apparently acute-onset lesions of the SDFT occasionally occur in show jumpers, especially those of international standard. Evaluation of the posture of the limb and the presence of heat, pain, and swelling are important for accurate diagnosis. Clinical signs associated with these injuries can vary markedly. Substantial lesions of the SDFT can develop without detectable lameness, whereas a large tear can result in acute, severe, non-weight-bearing lameness. Bilateral tears may result in extreme distress, a reluctance to move, and a laminitic-like stance. In event horses, lameness can develop after the speed and endurance phase of a Three Day Event, associated with SDF tendonitis, but no clinical signs may suggest the injury. Swelling or localized heat and pain may take several days to develop despite improvement or resolution of the lameness. Therefore careful reappraisal of the horse over the next few days is strongly recommended if an event horse develops an acute-onset, forelimb lameness for which no diagnosis can be identified.

Rupture of the SDFT results in hyperextension of the fetlock with normal foot placement. Elevation of the toe with normal angulation of the fetlock indicates disruption of the deep digital flexor tendon (DDFT). Hyperextension of the fetlock and elevation of the toe reflect laceration or rupture of the SDFT and the DDFT. Sinking of the fetlock to the ground indicates disruption of the suspensory apparatus, with or without the flexor tendons.

Severe lameness and distress, with hyperextension of the fetlock, without obvious swelling in the metacarpal region suggest rupture of the SDFT at the musculotendonous junction. This injury occurs most commonly in steeplechasers. Rupture of the SDFT usually is a sequela to a previous injury; therefore the tendon is generally chronically enlarged. Detection of the rupture is easiest at the peracute stage, before exudate and hemorrhage fill the deficit. The site of rupture is usually in the midmetacarpal region.

Desmitis of the ALDDFT usually causes acute-onset, moderate-to-severe lameness with rapid development of

soft tissue swelling in the region of the ligament. However, recurrent injuries can develop with no detectable alteration of a chronically enlarged ligament. The degree of lameness associated with a SL injury varies from mild to moderate but may be worse if a concurrent fracture of the second or fourth metacarpal bone or of the apex of a proximal sesamoid bone exists, and these structures should be evaluated carefully. Some severely lame horses with proximal suspensory desmitis have no palpable abnormalities.

Each of the tendons and ligaments in the metacarpal region should be palpated carefully, from proximally to distally, with the limb bearing weight and picked up. The size, shape, and consistency of the tendons and ligaments and any pain on palpation should be carefully assessed. With severe SDF tendonitis, the horse may be distressed, and peritendinous edema rapidly develops, which makes accurate palpation of the tendon difficult. Partial rupture may be associated with a palpable soft defect in the tendon. Bilateral SDF tendonitis sometimes occurs, with the only detectable palpable abnormality being slight enlargement of each tendon and rounding of its margins. The clinician must be aware of this, because these lesions may be missed if one assumes that because the limbs feel symmetrical, the tendons are normal.

A caudal radial osteochondroma or exostosis may cause episodic acute severe lameness associated with dorsal tearing of the DDFT. When lameness is apparent there may be distention of the carpal sheath and/or pain on passive flexion of the carpus. Lameness and other associated clinical signs may resolve rapidly.

Fractures of the Distal Aspect of the Limbs

A fracture of the lateral, or more rarely the medial, condyle of the third metacarpal or metatarsal bone results in acute-onset, severe lameness. If the fracture is incomplete and nondisplaced, no palpable abnormality may be detectable, although some effusion in the metacarpophalangeal joint usually develops within 12 to 24 hours. The horse may resent fetlock flexion; however, some horses become so distressed that in the acute phase, determining whether pressure or joint manipulation causes pain is impossible. The same can apply for a fracture of the proximal phalanx.

Subluxation of the metacarpophalangeal joint occasionally occurs, with disruption of a collateral ligament, with or without an associated fracture. The horse may be very lame, but during normal load bearing the joint may appear to be aligned normally. Instability of the joint may be detectable only with the joint stressed with the limb not bearing weight.

Feet

Trauma to the palmar aspect of the pastern may result in an innocuous skin wound but severe damage to the underlying soft tissue structures. The branches of the SDFT, the DDFT, and the digital flexor tendon sheath are particularly vulnerable. Posture of the limb should be carefully assessed to determine which structure or structures may be involved.

An overreach injury on the bulb of the heel can result in severe, deep-seated bruising and lameness, especially on hard ground. Injuries of the foot are common, especially in event horses. The differential diagnosis should include subsolar hemorrhage (especially corns), nail bind, a subsolar abscess, and a fracture of the distal phalanx.

If the horse shows any reaction to percussion of the foot or pressure applied with hoof testers, the shoe should be removed for further exploration of the foot. If the horse is very lame, removal of each nail individually using nail pullers may be preferable to levering off the shoe. The absence of reaction to hoof testers and normal digital pulse amplitudes does not preclude the existence of either laminitis or a subsolar abscess.

Hindlimb Injuries

When one examines a horse with acute hindlimb lameness that developed during exercise, consideration should always be given to tying up, even if the hindlimb musculature feels soft, local pain cannot be elicited, and the horse is not unduly distressed. The clinical manifestations of tying up vary considerably from acute, severe bilateral or unilateral hindlimb lameness with obvious firmness of the muscles of the hindquarter, with or without swelling, to a moderate unilateral hindlimb lameness that developed after the horse was not moving as freely as normal, with no detectable palpable abnormality. This lameness may persist for several hours but usually resolves within 12 to 18 hours. Occasionally, tying up can affect forelimbs, alone or together with the hindlimbs.

Measurement of substantially raised serum creatine kinase concentration 3 to 24 hours after the onset of lameness may be the only way to reach a definitive diagnosis. Alternatively, a horse may not be moving as freely as normal during a competition and subsequently may be withdrawn; further clinical signs may not develop.

Major hindlimb muscle rupture of quadriceps, semimembranosus, gastrocnemius, adductor, gracilis, or abdominal muscles results in severe lameness and distress, but diagnosis may be difficult. Careful palpation may reveal a site of rupture. Detection of acute muscle strains may be possible when superficial muscles are involved. Pain on palpation and sometimes swelling may be present; however, this is not always the case, and evaluation of deep muscles is limited. Swelling may become more apparent over the next several days.

Stifle trauma is common in horses that jump fixed fences at speed, even if the rider cannot recollect the horse hitting a fence. Lameness caused by a fracture may be sudden and severe in onset, and the horse may pull up, but in some horses it does not become apparent until the horse has finished.

Because the cranial aspect of the stifle is relatively poorly covered with soft tissues, the bones are particularly susceptible to bruising or fracture (Figure 13-4). The degree of pain on palpation does not necessarily reflect accurately the severity of the injury. Development of femoropatellar or femorotibial effusion or marked periarticular soft tissue swelling suggests a fracture. Sometimes a displaced fragment of bone can be palpated. The superficial location of the femoropatellar joint capsule also makes it vulnerable to puncture and the introduction of infection, and effusion and severe lameness may develop rapidly.

Most horses with stifle injuries require radiographic examination to establish or confirm the presence of a fracture. Although lameness associated with bruising may initially be severe, the horse generally rapidly improves within 24 to 48 hours, whereas with most fractures the lameness usually persists unchanged. The horse may be reluctant to

Fig. 13-4 • Cranioproximal-craniodistal oblique radiographic image of right stifle of an event horse that hit the penultimate fence at the World Equestrian Games. The horse completed the course, pulled up slightly lame, and was very lame within a few hours. The arrows show an articular fracture of the medial pole of the patella.

extend the stifle and tends to stand with the limb semi-flexed and the weight on the toe, a posture also typical of severe foot pain. Occasionally, severe ligamentous injury that cannot be detected radiologically occurs in the stifle.

Periarticular hemorrhage around the patellar ligaments can result in acute pain and lameness characterized by a shortened cranial phase of the stride at the walk, but less severe lameness at the trot. Swelling may be subtle, resulting in loss of definition of the patellar ligaments; diagnosis is dependent on ultrasonographic examination.

Rupture of the fibularis tertius usually results from a traumatic episode, with the limb getting trapped in an extended position, and results in a severe lameness with the horse unwilling to load the limb fully. Passive extension of the hock is pathognomonic.

Acute injuries to the hock are uncommon, unless the horse has a severe fall resulting in damage to the hock joint capsules and the collateral ligaments or a lateral malleolar fracture of the distal aspect of the tibia. The horse usually is severely lame and rapidly develops distention of the tarsocrural joint capsule and periarticular soft tissue swelling. Radiographic examination is indicated to determine the extent of the damage. Less commonly, slab fractures of the central or third tarsal bone or incomplete sagittal fractures of the talus cause acute, severe lameness, often with no localizing clinical signs. Kick injuries may result in a fracture. Whereas intuition would suggest that kick wounds should most likely involve the lateral aspect of the tarsus, often the medial tarsal or proximal metatarsal region is involved. Careful interpretation of radiographs may be necessary to detect small fragments displaced from the sustentaculum tali, on the distal medial aspect of the calcaneus.

Displacement of the SDFT from the tuber calcanei may occur suddenly, resulting in marked distress, especially if the tendon continues to move on and off the tuber calcanei. The tendon may slip laterally, or less commonly medially, and occasionally splits. Peritendonous soft tissue swelling develops rapidly. The horse is reluctant to bear weight on the limb and characteristically shows extreme distress,

caused by pain or instability. Careful palpation usually confirms the diagnosis, although acute soft tissue swelling may make this difficult in the initial period after injury.

Periarticular cellulitis of the tarsal region results in an extreme lameness associated with the rapid development of extensive soft tissue swelling, which is exquisitely sensitive to touch (see Chapter 107). The horse is often lamer than with a fracture, and swelling is more extensive than with synovial infection.

Injuries to the soft tissue structures of the metatarsal and pastern regions are less common than those of the metacarpal and forelimb pastern regions. Suspensory branch injuries are the most common injuries resulting from direct blunt trauma. Acute tears of the DDFT may occur within the digital flexor tendon sheath, with rapid development of effusion. Fractures of the third metatarsal bone and phalanges are also less common than in the forelimbs, except in barrel racing or cutting horses or polo ponies. Plantar process fractures of the proximal phalanx are rare but do occur in racehorses and result in moderate-to-severe lameness, with pain on manipulation of the fetlock, effusion, and in some horses periarticular soft tissue swelling, especially on the plantar aspect. Stability of the fetlock should be assessed carefully.

Stress Fractures

In young Thoroughbred racehorses the possibility of a fatigue or stress fracture must always be considered. The most common sites are the humerus, radius, ilial wing, tibia, third metacarpal bone, and tarsus. With the exception of ilial wing fractures, in which asymmetry of the tubera sacrale and pain on palpation in this area may be obvious, localizing clinical signs may otherwise be absent. A definitive diagnosis can rarely be made by clinical examination alone.

Hemarthrosis

Hemarthrosis may occur in any joint and results in acute-onset, non-weight-bearing lameness associated with distention of the joint capsule. Lameness often improves rapidly within the following 48 hours. Diagnosis is based on ultrasonography and synoviocentesis. Draining blood from the joint produces rapid relief of clinical signs.

TRANSPORTATION

In any horse with severe lameness in which making a tentative diagnosis based on a preliminary but thorough clinical examination is not possible, a decision has to be made about whether the horse is fit to travel, whether any risks are involved in travel, and whether the horse should be stabled as close as possible and be reassessed later or the following day (if this is practical). Whether the horse is insured should be established, together with the terms of the insurance policy.

The majority of horses can be taken safely to the nearest adequate diagnostic facility, which ideally should have a loading ramp, a veterinarian experienced in orthopedics, facilities for hospitalization, and high-standard radiographic, ultrasonographic, and possibly nuclear scintigraphic equipment.

Facilities for orthopedic surgery are not necessarily essential, although they are desirable, because the first step

must be to reach an accurate diagnosis. When a diagnosis has been reached, the limb may then be appropriately supported to minimize risks of exacerbating the injury, if the horse is to be treated conservatively; during induction of general anesthesia; or for transfer to a suitable surgical facility. If a hindlimb fracture is suspected, the horse should be tied up (cross-tied). For transport for further diagnostic investigation or surgical treatment the injured limb should usually be supported using a Robert Jones bandage,¹ with or without splints, or an appropriate commercial splint, bearing in mind the proposed site of injury² (see Chapters 86 and 104). For forelimb injuries the horse should ideally travel facing backward, although some low-loading ambulances are not designed for loading from the front.³ When possible a low-loading trailer should be used, but if this is not available, the ramp of the vehicle should be placed on a slope to minimize the gradient for loading and unloading. If a diagnosis has been made for a horse with an injury that requires rapid surgical treatment, the limb should be supported in the most appropriate way and the horse referred to the nearest surgical facility, or to the best surgical facility in close proximity to the horse's place of origin, or to the person with the most expertise and experience dealing with that kind of injury. Provided that the limb is adequately immobilized and adequate pain relief is possible, the horse should be fit to travel several hours safely and humanely.

GUIDELINES FOR HUMANE DESTRUCTION OF AN INJURED HORSE

If the horse is insured for all risks of mortality, owners, trainers, and other interested people may request humane destruction. The American Association of Equine Practitioners (AAEP) and the British Equine Veterinary Association (BEVA) have issued guidelines indicating the requirements that should be fulfilled to satisfy a claim under a mortality insurance policy. Nonetheless, the decision to advise an owner to destroy a horse on humane grounds must be the responsibility of the attending veterinary surgeon, based on the assessment of clinical signs at the time of the examination or examinations, regardless of whether the horse is insured. The veterinary surgeon's primary responsibility is always to ensure the welfare of the horse. On occasion the attending veterinary surgeon will advise euthanasia, but such a decision may not necessarily lead to a successful insurance claim. It is important that all parties be aware of

these potential conflicts of interests before a horse is destroyed. The owner's responsibility is to ensure compliance with any policy contract with an insurer.

The AAEP has issued the following guidelines for recommending euthanasia:

The AAEP recommends that the following criteria should be considered in evaluating the immediate necessity for intentional destruction of a horse. It should be pointed out that each case should be addressed on its individual merits and that the following are guidelines only. Not all criteria must be met in each case.

1. Is the condition chronic, incurable and resulting in unnecessary pain and suffering?
2. Does the immediate condition present a hopeless prognosis for life?
3. Is the horse a hazard to itself or its handlers?
4. Will the horse require continuous medication for the relief of pain for the remainder of its life?

Justification for euthanasia of a horse for humane reasons should be based on medical grounds, not economic considerations; and further the same criteria should be applied to all horses regardless of age, sex or potential value.

The BEVA guidelines for compliance for a mortality insurance policy are as follows:

That the insured horse sustains an injury, or manifests an illness or disease, that is so severe as to warrant immediate destruction to relieve incurable and excessive pain, and that no other options of treatment are available to that horse, at that time.

If immediate destruction cannot be justified, then the attending veterinary surgeon should provide immediate first aid treatment before:

1. Requesting that the insurance company be contacted, or, failing that
2. Arranging for a second opinion from another veterinary surgeon.

It is essential that the attending veterinary surgeon keep a written record of the injuries sustained by the horse, its identification, and the date, time, and place. The owner or agent should whenever possible sign a form consenting to euthanasia. Insurance companies frequently require some form of examination after death and may request an independent postmortem examination, and this must be borne in mind when arranging for disposal of the carcass.

Chapter 14

The Swollen Limb

Sue J. Dyson

The development of diffuse or more localized swelling in one or more limbs can present a diagnostic challenge, requiring a systematic approach to identify the cause. Although the metacarpal, metatarsal, and pastern regions

are most commonly affected, an entire limb may be swollen, or swelling may initially be restricted to the antebrachium or crus or the carpus or tarsus, with swelling subsequently spreading distally. This chapter discusses an approach to diagnosis and management but does not provide exhaustive differential diagnoses and treatments. Some conditions are discussed in more detail in other chapters.

DIAGNOSIS

Many stabled horses develop some degree of enlargement of the distal limbs, especially the hindlimbs, that dissipates with work. Termed *filled legs* or *cold edema* (stocked-up,

stoved-up), this swelling may be controlled by applying stable bandages and is of no consequence.

History

Accurate diagnosis of the cause of limb swelling requires knowledge of the history.

- Was the problem sudden or gradual in onset?
- What is the duration of the swelling?

It may be pertinent to establish when the owner last thought that the horse was normal, especially in horses that are not inspected regularly while kept at pasture. The actual duration of swelling may be longer than the owner recognized. The veterinarian also should bear in mind that some owners are remarkably unobservant, despite maintaining that they look at and groom the horse thoroughly daily.

- Were any swellings preexisting?
- What was the initial distribution of the swelling, and has this changed?
- Has similar swelling appeared previously? Lymphangitis may be a recurrent problem.
- Does any history of trauma exist?
- Has the limb been bandaged, or have boots or bandages been used for exercise? Overly tight bandages can rapidly result in severe cellulitis, skin excoriation, and hair loss. Sand or grit inside a boot can provoke severe skin inflammation and diffuse soft tissue swelling.
- Has the horse had tendonitis or desmitis? Recurrent injury may be much more severe and result in diffuse swelling, prohibiting accurate palpation of the injured structure.
- Has the horse had any other recent clinical problems? Strangles may predispose to purpura hemorrhagica.
- Does the horse show any other clinical signs, and could the limb swellings reflect systemic disease?
- Is the horse lame, and when did lameness develop relative to the recognition of swelling? If swelling preceded the lameness, more than one problem may exist.
- Have there been any recent injections?
- Has the horse received any treatment, and what was the response? Has anything topical been applied to the limb that may be irritant?

Swelling in a single limb usually reflects a local problem, whereas swelling in several limbs may be caused by systemic disease or a primary skin problem. The differential diagnosis should include the following: subsolar abscess (see Chapter 28); mud fever or scratches; scabby skin lesions on the palmar aspect of the fetlock; other bacterial pyodermas; hemorrhage or thrombosis (see Chapter 37); desmitis or tendonitis (see Chapters 69 to 72); cellulitis associated with superficial digital flexor tendonitis (see Chapter 69); skin necrosis and cellulitis after topical application of proprietary products; infected tendon or tendon sheath; cold edema; cellulitis caused by trauma or infection; fracture; hypertrophic osteopathy (see Chapter 37); muscle rupture (see Chapter 13); muscle trauma resulting in compartment syndrome (see Chapter 83); lymphangitis; photosensitization; equine viral arteritis; heart failure; and hypoproteinemia.

Clinical Examination

A systematic clinical examination should be performed by careful observation and palpation. The veterinarian should

assess the horse's posture, demeanor, and attitude. Depression may reflect pain or infection.

- Is the horse febrile? The clinician should determine whether one or more limbs are involved.
- What is the distribution of the swelling? Is it localized or more diffuse? Swelling associated with a subsolar abscess is usually diffuse and involves the pastern and metacarpal or metatarsal region, extending a variable degree proximally, and is symmetrically distributed around the limb. In contrast, swelling associated with direct trauma may be restricted to the metacarpal region in the acute phase and only later spread distally, and may be most extensive on one aspect of the limb.
- Does the swelling relate to a joint or to a long bone and the surrounding soft tissues?
- Where is swelling maximal? Is swelling predominantly on one side of the limb, which may reflect trauma, because of the horse becoming cast?
- Does the metacarpal (metatarsal) region have a straight palmar (plantar) contour? Diffuse swelling in the metacarpal region is unlikely to reflect superficial digital flexor tendonitis if the palmar aspect of the limb is straight.
- Is the swelling cool, warm, or hot? Hot swelling is most likely to be associated with infection.
- Is the swelling tense, often reflecting infection, or soft?
- Is evidence of pitting edema present?
- Does light digital pressure or firm pressure elicit pain? Pain caused by only light pressure is often associated with cellulitis caused by infection (e.g., peritarsal cellulitis) or less commonly by intratendinous infection.
- How does the location of pain relate to the site of maximal swelling?
- How easily can underlying anatomical structures be palpated, and does palpation cause pain? The veterinarian should note that scabby skin lesions overlying soft tissue swelling can in themselves be remarkably painful.
- Does a draining tract suggest an abscess, cellulitis, or infectious osteitis or osteomyelitis?
- Does joint manipulation cause pain?
- Do any skin lesions exist through which infection may have entered? This may not be readily apparent in a horse with a long hair coat, and clipping may be necessary. In a horse kept at pasture the limb may be caked in mud, and thorough cleaning may be necessary before an accurate clinical examination can be made.
- Do any other skin lesions reflect a primary dermatological problem? The clinician should try to categorize any lesions identified.

The digital pulse amplitudes should be assessed: any increase highly suggests a primary foot problem. The response to pressure and percussion applied with hoof testers should be evaluated. Pulse rate, the quality of the peripheral pulses, capillary refill time, and careful auscultation of the heart and lungs should reveal whether a primary cardiac problem exists.

The mucous membranes should be examined for evidence of petechial hemorrhages, which can be seen with

purpura hemorrhagica. The veterinarian should relate the swelling to the color of the limbs; swelling confined to white limbs may result from photosensitization.

The clinician should establish the degree of lameness and bear in mind that mild stiffness may result from extensive limb swelling and mechanical restriction. Extremely severe lameness often reflects infection—periarticular (e.g., peritarsal cellulitis; see Chapters 44 and 107), intraarticular, intrathecal, intratendonous, or subsolar. A horse with a fracture may be less lame. Severe lameness may also be associated with an acute muscle tear or hemorrhage. Although there may be no obvious swelling in the acute stage, diffuse filling of the affected limb may develop over the following 24 to 48 hours distal to the site of injury.

The results of this clinical examination should suggest the likely causes of the swelling, but definitive diagnosis might not be possible without further investigation. This may include radiography, ultrasonography, routine hematological testing, measurement of total protein and fibrinogen, and liver enzyme levels if indicated. Paired serum samples may be required to confirm equine viral arteritis. Treating the horse symptomatically to reduce the soft tissue swelling may be helpful to facilitate more accurate palpation. This may include the use of nonsteroidal anti-inflammatory drugs (NSAIDs), hydrotherapy, poulticing or leg sweats, bandaging, and walking, with or without antimicrobial medication. Without evidence of a primary infectious process the response to corticosteroids may be helpful diagnostically, because limb filling may be an immune-mediated response. The clinician should be prepared to make repeated examinations if a primary diagnosis is not readily apparent.

Early periosteal new bone associated with hypertrophic osteopathy is readily overexposed, and greatly reduced exposure factors are required for its radiological detection. On the first day of examination the results of radiographic and ultrasonographic examinations may be misleading, and repeated examinations may be necessary. After trauma, laceration, or both to the antebrachium, crus, and metacarpal or metatarsal regions, delayed-onset lameness caused by an occult spiral fracture of the radius, tibia, or third metacarpal or metatarsal bones is possible. Many oblique radiographic images or follow-up examination may be necessary to identify the fracture. If extensive cellulitis occurs around a joint or tendon sheath, but intraarticular or intrathecal infection is suspected, the examiner should be cautious about performing synoviocentesis through infected tissues, because iatrogenic intraarticular or intrathecal infection may ensue. If skin lesions are identified as a possible primary cause of limb swelling, but these fail to respond to topical or systemic treatment, obtaining skin biopsies for culture and histological examination or seeking specialist advice from a dermatologist may be necessary.

MANAGEMENT

Mud Fever

Mud fever (scratches or pastern dermatitis) is associated with bacterial or fungal skin infection and usually is restricted to the palmar or plantar aspect of the pastern but sometimes extends farther proximally if severe. Mud fever is associated with many excoriated skin lesions, which may

develop severe crusting. Deep fissures may develop in the skin, especially if the condition goes unrecognized or in horses with many skin folds in the pastern region. Extensive edematous swelling often extends up the metacarpal and metatarsal regions. If the condition is mild, no associated lameness may occur, but severe lesions are associated with marked stiffness. The condition can occur in horses kept out in wet, muddy conditions or in horses that are stabled but work in a muddy environment. Certain soil types seem to be associated with a higher occurrence. Some horses seem prone to recurrent episodes, although this may in part reflect management practices. The condition is difficult to manage if the horse is left in wet, muddy pasture, and it must be stabled. The affected areas should be clipped and thoroughly cleaned with chlorhexidine solution. The scabs should be softened to facilitate removal. If the condition is mild, no further treatment may be required, but if the condition is more severe, daily topical application of lanolin-based emollient cream with trimethoprim and sulfadiazine and dexamethasone is indicated, sometimes combined with systemic antimicrobial treatment. Alternatively, a proprietary topical preparation can be used. The limbs should be carefully cleaned and dried after exercise.

Scabs on the Palmar Aspect of the Fetlock

Some horses seem prone to develop many small skin scabs on the palmar or plantar aspects of the fetlock. The scabs appear to be related to work on specific surfaces, which presumably cause skin irritation and subsequent bacterial infection. These skin lesions are often associated with diffuse swelling and can be exquisitely painful. The lesions rarely resolve spontaneously but usually respond to penicillin therapy.

Cellulitis Caused by Trauma

Direct trauma to a limb may result in extensive edematous soft tissue swelling unassociated with infection. If skin abrasion is concurrent, the site of the wound relative to synovial structures susceptible to infection must be evaluated carefully. Lameness may vary in degree, but if severe, the possibility of fracture must be considered. If little soft tissue covers the underlying bones, radiographic examination is prudent to eliminate the possibility of a fracture. With primary cellulitis, treatment with NSAIDs, rest, and controlled exercise is usually all that is required. A variety of commercial boots and wraps are available that provide hot and cold therapy combined sometimes with pulsed pressure, which may be beneficial in reducing soft tissue swelling. The limb should be bandaged between treatments.

Cellulitis Caused by Infection

Cellulitis associated with infection may result from blunt trauma, a penetrating wound, previous injection, or recent surgery, but in many horses no underlying cause is identified.^{1,2} Thoroughbred racehorses may be most susceptible.^{2,3} It usually results in fairly extensive soft tissue swelling, which tends to be warmer and more painful than swelling from noninfectious cellulitis (see Figure 5-8). Associated lameness may also be severe, depending in part on the location of infection. If the infection is untreated, abscessation may develop in muscular areas and may require surgical drainage. Cellulitis may also be concurrent with

Fig. 14-1 • Photographs before (A) and after (B) antibiotic and corticosteroid therapy of an aged Thoroughbred broodmare with suspected purpura hemorrhagica. Before therapy all four limbs were edematous and erythematous, and there was diffuse crusting and with serum discharge. Signs were not limited to the distal limbs; the mare had intermittent gastrointestinal pain and hyperemia of mucous membranes. (Courtesy Mike W. Ross.)

infectious osteitis or osteomyelitis (see Chapter 37). Horses with acute infectious cellulitis usually respond well to systemic broad-spectrum antimicrobial treatment (e.g., crystalline penicillin and gentamicin), unless clostridial organisms are involved (see Chapter 83). The most common bacterial isolates are *Staphylococcus aureus* and *Streptococcus* species. Analgesia may be necessary and should be used to try to prevent secondary laminitis in the contralateral limb.

Lymphangitis

So-called lymphangitis occurs more commonly in hindlimbs than forelimbs and is often unilateral but may be bilateral. Diffuse soft tissue swelling occurs throughout the limb, often extending to the distal aspect of the limb from immediately below the stifle. The superficial lymphatic vessels may appear more prominent than usual. Serum may ooze through taut skin. The degree of swelling usually results in mechanical stiffness that improves with progressive walking. Careful inspection may reveal some small skin lacerations, often in the more distal part of the limb. Once a horse has had a severe attack of lymphangitis, it seems prone to recurrence, often after seemingly innocuous skin abrasions. Although the condition appears to be triggered by infection, antimicrobial treatment alone is inadequate and usually must be combined with long-term corticosteroid treatment (dexamethasone 0.05 to 0.2 mg/kg once daily intravenously or intramuscularly, using the

lowest dose necessary to control edema, and replacing with prednisolone 0.5 to 1 mg/kg intramuscularly or by mouth twice daily, when the dexamethasone dose is <0.04 mg/kg), together with aggressive hydrotherapy and walking exercise, with or without bandaging and topical application of leg sweats. Bandaging the metatarsal region in the face of more proximal limb swelling tends to result in persistent proximal limb swelling that cannot move distally. Although prompt aggressive treatment may resolve clinical signs, persistence of marked filling for more than a week may result in chronic enlargement of the limb. Ulcerative lymphangitis occurs much less frequently and is caused by bacterial or fungal infection.

Purpura Hemorrhagica

Purpura hemorrhagica usually occurs as a sequela to previous streptococcal respiratory infection but occasionally follows other antigenic stimuli. Purpura hemorrhagica results in extensive submucosal petechial hemorrhages, evident clinically in the mucous membranes but actually more widespread, including muscle and viscera. Facial swellings and limb edema may be extensive (Figure 14-1). The horse is usually depressed, inappetent, and pyrexemic. Purpura hemorrhagica is an acute, probably immune-mediated, necrotizing vasculitis. Aggressive treatment with penicillin and corticosteroids (see the previous discussion) is required.

SECTION 2

Diagnostic Imaging

| Chapter 15

Radiography and Radiology

Sue J. Dyson

Radiography is the acquisition of radiographic images; radiology is the study and interpretation of those images. Radiography is an important part of the diagnostic armamentarium in the evaluation of lameness. Its most important role is to give information about bones and joints. However, it also can provide information about soft tissues, most particularly tendon, ligament, and joint capsule insertions. If radiography is to be used properly, then the area under investigation must be evaluated comprehensively and appropriately. A sufficient number of views, all which have been appropriately centered and exposed, should be obtained.

Obtaining high-quality radiographic images requires attention to detail. The horse must be correctly positioned and adequately restrained or sedated. For most weight-bearing examinations the horse should stand with the cannon bone of the limb to be examined in a vertical position. The horse should be standing on all four limbs, not resting a limb. The area under investigation should be cleaned to remove any surface dirt. For examinations of the foot, the shoe should be removed (if possible) to facilitate proper paring of the sole and frog, to ensure it is adequately clean, and to avoid superimposition of a radiodense shoe over the distal phalanx and navicular bone. The tail should be tied to facilitate correct positioning of the cassette or imaging plate when the stifle and hock regions are examined.

RADIOGRAPHIC DETAIL

The aim is to obtain as highly detailed radiographic images as possible. The detail that can be obtained is influenced by a number of factors, including those listed in [Box 15-1](#).

Image Resolution

Image resolution is the objective measurement of how much detail can be provided by a film-screen combination and is measured in line pairs per millimeter. Resolution indicates the size of the smallest object that the system will record (i.e., the smallest distance that must exist between two objects before they can be distinguished as two separate entities). Image definition cannot be quantified but is the subjective impression of the amount of detail that can be seen on a radiograph.

Image Contrast

Contrast is the degree of definition on a radiographic image between adjacent structures of differing radiopacities. Opacity or radiopacity is the degree of whiteness of the object being radiographed. The denser the physical structure, the greater the degree to which the tissue absorbs x-rays, and the more opaque it appears on a radiograph.

Exposure Factors

Exposure factors affect the opacity and contrast of the radiographic image. The kilovoltage governs the quality and intensity of x-rays and affects both contrast and opacity. The quantity of x-rays reaching the x-ray film or imaging plate is the product of milliamperage and time and is also influenced by the focus-film distance (FFD), according to the inverse square law. The following equation is used to calculate the exposure of a change in distance:

$$\text{Old mAs} \times \frac{(\text{New FFD})^2}{(\text{Old FFD})^2} = \text{New mAs}$$

The milliamperere-seconds and FFD affect the opacity of the image, not the contrast.

Exposure Latitude

Exposure latitude is the degree of overexposure or underexposure that can be tolerated in a correctly developed film and still produce an image of acceptable radiographic quality. A low kilovoltage yields high contrast with low latitude, whereas a high kilovoltage results in low contrast but has wide latitude. For good bone detail the kilovoltage should be less than 70 kV. Attenuation of the x-ray beam depends heavily on the atomic number of the tissues, and it is desirable that photoelectric absorption predominate. Increasing the kilovoltage also results in more forward scatter. The use of computed or digital radiography potentially results in greater latitude for a single exposure.

To obtain a radiographic image with the same opacity as the original but with decreased contrast, the milliamperere-seconds are halved and the kilovoltage is increased by 15% (approximately 10 kV). To increase the contrast but maintain the opacity, the milliamperere-seconds are doubled and the kilovoltage is reduced by approximately 15%.

Image Sharpness and Resolution

Lack of image sharpness can be caused by a number of factors, including movement of the horse. Short exposure times help to reduce the risk of movement blur. Reducing the FFD can increase the amount of x-rays reaching the horse, and therefore the exposure time could be reduced. However, reduction of FFD results in an increase in geometric indistinctness or *penumbra*. Image blur also may be the result of poor screen-film contact. Contact can be tested by placing a wire mesh on top of the cassette and making an exposure using a large FFD. Any loss of image sharpness is the result of poor film-screen contact.

BOX 15-1

Factors That Influence Radiographic Images

- **Film screen combination** (with conventional radiography). High-definition screens for use with single-emulsion and relatively slow film provide the best definition in the distal limbs. When higher exposure factors are required to gain adequate penetration of the more proximal parts of the limb, rare earth screens are required to minimize exposure times and thus reduce the risk of movement blur.
- **Proper contact between the film and the screen.** Old screens become warped, which results in loss of image quality. Damaged imaging plates result in artifacts.
- **Cleanliness of the screens.** Dust and hair accumulate easily within cassettes and imaging plates, resulting in radiopaque artifacts and lines on the films. Screens or imaging plates must be cleaned regularly. Careful technique is essential to reduce the risk of dust buildup.
- **Power of the x-ray machine.** The use of high-definition screens is possible only with x-ray machines capable of an output of 100 kV and 100 mAs. Otherwise, exposure times are too long, resulting in movement blur.
- **Choice of appropriate exposure factors.** This step is less critical with digital radiography when postprocessing can be used.
- **Use of the correct focus-film distance (FFD).** X-rays obey the inverse square law, so that an alteration in the FFD potentially has a big effect. Single-emulsion film and computed or digital radiographic imaging plates are particularly sensitive to a slight change in the FFD.
- **Exposure time.** The exposure time should be as short as possible to reduce movement blur.
- **Use of grids.** Grids are required in areas with a large amount of soft tissue, which results in scattered radiation.

The use of a grid requires a higher exposure factor. If a focused grid is used, the x-ray beam must be perpendicular to the grid and centered on it, and the correct FFD should be used. Parallel grids have slightly more latitude when an

FFD of more than 120 cm is used. The higher the grid ratio and lines per centimeter, the more effective the grid is in reducing scattered radiation, but the higher the grid factor. The grid factor denotes how much an exposure must be increased from nongrid values for comparable opacity. For example, if the grid factor is 2, then the milliamperere-seconds (mAs) should be doubled.

- **Lead.** Lead is placed behind the cassette when large exposures are used to reduce the amount of backscatter.
- **Collimation of the x-ray beam.**
- **Use of stationary cassette holders when possible and practical to reduce movement of the cassette.**
- **Size and shape of the horse.** These factors become particularly important when the thoracolumbar region is examined. The amount of muscle mass and fat influence the exposure factors; with very large horses there is a risk of the radiographic images becoming flat as the exposure is increased. The shape of the horse's barrel also influences how closely the cassette can be placed to the back and thus influences magnification. The use of an aluminum wedge filter allows the intensity of the beam to be reduced in specific areas and is of particular value for examining areas with a marked change in soft tissue thickness from one side of the film to the other (e.g., the dorsal spinous processes in the thoracolumbar region, the shoulder, and the stifle).
- **The physics of computed and digital radiography** makes it more difficult to obtain high-quality images where there are very big differences in opacities of adjacent structures; this problem seems to be magnified in the caudal thoracic and lumbar regions of large horses.
- **Amount of soft tissue swelling.** If marked periarticular soft tissue swelling is present, higher exposures are required to achieve adequate penetration. The use of a grid in these circumstances helps to reduce scattered radiation.
- **Cooperation of the horse.**

Image resolution also can be influenced by the focal spot size of the x-ray machine. High-output x-ray machines usually have different size focal spots. A small focal spot (e.g., 0.6 mm) usually results in better image resolution, but an increased exposure time is required to achieve the same milliamperes. When movement is likely to be a problem (e.g., proximal limb examinations), a larger focal spot (1.5 to 2.0 mm) is preferable to reduce exposure times.

Film and Screen Factors

Relative speed ratings of screens and distance factors must be considered when exposure factors are being selected. Speed classification of film-screen combinations allows comparison of systems from different manufacturers. Some manufacturers use 100, 200, 400, and so on, and others use 2, 4, 8, and so forth, but the interrelationship is the same. Speed 8 screens require half the exposure (milliamperere-seconds) needed for speed 4 screens; speed 200 requires twice the exposure (milliamperere-seconds) of speed 400. Although the same exposures are required to provide the same image opacity using similar film-screen speeds, the detail and resolution may vary. Generally when only one screen from a pair is used (when using single-emulsion film), the speed of the system will halve. Thus if one screen from a pair rated 400 is used, the speed will be 200.

RADIATION SAFETY

Radiation safety (i.e., ensuring that personnel around the horse do not receive doses of radiation) is essential. Different codes of practice apply in various countries, but the basic principles are summarized in [Box 15-2](#).

RESPONSE OF BONE TO STIMULI: WOLFF'S LAW

Correct interpretation of radiographic images requires knowledge of the ways in which bone responds to various stimuli. Bone models according to Wolff's law: it models according to the stresses placed on it so that it can be functionally competent with the minimum amount of bone tissue. The use of the terms *modeling* and *remodeling* creates considerable confusion because usage differs in histology and radiology. Histologically, *bone remodeling* refers to resorption and formation of bone that is coupled and occurs in basic multicellular units. This regulates the microstructure of bone without altering its shape and is a continuous process, replacing damaged bone with new bone. Thus remodeling cannot be appreciated radiologically. Radiologically, the term has been used to describe reshaping of bone to match form and function (e.g., after fracture repair). Strictly speaking, the term *modeling* should be used to describe the change in the shape of a bone as it adapts to the stresses applied to it.

BOX 15-2

Basic Principles of Radiation Safety

- The number of people present during radiography should be kept to the absolute minimum required to restrain the horse, position the limb and the x-ray cassette, and obtain the radiograph.
- Appropriate restraint or sedation of the horse is essential to ensure it remains still during exposures. This practice will limit the number of repeat exposures needed.
- Regarding collimation of the x-ray beam, use of a light beam diaphragm permits maximum collimation. No part of any attending person, even if covered with protective clothing, should be placed in the primary x-ray beam. Protective lead clothing protects from scattered radiation only, not the primary beam. The primary beam continues beyond the horse and cassette, and personnel standing on the opposite side also are at risk.
- All personnel who must remain present for the exposure must wear protective lead gowns. If near the primary beam, they should also wear protective lead gloves, hand and arm protection, and a thyroid protector.
- All protective clothing should be checked annually and replaced when necessary.
- All personnel working with and around the x-ray machine must be monitored using a film badge system.

Bone is a dynamic tissue, constantly reacting to the stimuli that it receives both internally and externally. However, it takes time to respond, and a 40% change in bone density must occur before changes are evident radiologically. Therefore radiographic images, although anatomically accurate, are relatively insensitive in the early stages of a disease process. This is known as the radiographic *latent period*. It is critical to appreciate these limitations when interpreting radiographic images. Bone can be undergoing abnormal modeling without identifiable structural change. Once radiological abnormalities have developed, some will persist over the long term without necessarily being associated with ongoing pain. Thus in effect these changes remain as scars reflecting previous injury. Aging of such lesions is impossible, and assessing clinical significance must be evaluated in the light of the clinical signs.

Bone can react to stimuli in only a limited number of ways. Bone can produce new bone, such as periosteal new bone, endosteal new bone, cortical thickening, increased thickness of trabeculae, callus formation, osteophyte and enthesophyte formation, and the palisading periosteal new bone typical of hypertrophic osteopathy. New bone often results in what has been described radiologically as *sclerosis*: increased opacity of the bone, caused by either new bone being laid down within the bone or superimposition of new bone on the surface of the bone. More than one radiographic image usually is required to determine why a structure appears to have increased opacity (i.e., is sclerotic). Strictly speaking, however, sclerosis is a localized increase in opacity of the bone caused by increased bone mass within the bone. Unless this can be determined with certainty it is preferable to use the term *increased radiopacity*.

Osteolysis is resorption of bone resulting in a radiolucency. Again, a lag period, usually of at least 10 days, occurs between the onset of osteolysis and its radiological detection. Osteolysis occurs for a variety of reasons, including pressure, infection, as part of early fracture repair, and as

Fig. 15-1 • Dorsomedial-palmarolateral oblique radiographic image of the metacarpal region. Soft tissue swelling overlies periosteal new bone (arrows) on the middiaphyseal region of the second metacarpal bone.

part of the disease process in osteoarthritis, osteochondrosis, osseous cystlike lesions, and subchondral bone cysts. Bone destruction and resorption usually are seen more easily in cortical bone rather than cancellous bone because of the greater contrast.

Generalized demineralization, or osteopenia, of bone throughout the body rarely occurs in the horse. Localized demineralization in a single limb usually is the result of disuse and is characterized by thinning of the cortices and a more obvious trabecular pattern. The proximal sesamoid bones are particularly sensitive indicators of disuse osteopenia in the horse.

Focal demineralization and loss of bone may be caused by pressure—for example, as seen in chronic proliferative synovitis in the fetlock—resulting in erosion of the dorso-proximal aspect of the sagittal ridge of the third metacarpal bone (McIII). It may be the result of infection, invasion by fibrous tissue, or a neoplasm.

Cortical thickness changes (models) according to Wolff's law as an immature athlete develops into a mature, trained athlete. The dorsal cortex of the McIII and the third metatarsal bone becomes thicker. If a horse has marked conformational abnormalities, such as offset or bench knees, the bones model accordingly, with the lateral cortex of the distal limb bones becoming thicker.

Periosteal New Bone

Blunt trauma to bone can lead to subperiosteal hemorrhage, resulting in lifting of the periosteum away from the bone. This process may stimulate the production of periosteal new bone (Figure 15-1). Some bones, such as the second and fourth metacarpal and metatarsal bones, seem particularly prone to such reactions. There is individual variation among horses in susceptibility to such reactions. Usually a lag period of at least 14 days occurs between trauma and the radiological detection of periosteal new bone. Such

bone usually is much less dense than the parent bone; therefore soft exposures (or low kilovoltages) are essential for detection of this bone, which initially has a rather irregular outline. As the bone gradually consolidates and then models, it becomes more opaque and more smoothly outlined. Curiously, although a well-established splint exostosis would be expected to become inactive, many have increased radiopharmaceutical uptake (IRU) compared with the parent bone if examined scintigraphically.

Periosteal new bone can also develop as a result of fracture, infection, inflammation, and neoplasia. Inflammation of the interosseous ligamentous attachment between the second metacarpal bone and the McIII or the fourth metacarpal bone and the McIII caused by movement and loading can result in periosteal new bone formation and a splint exostosis. It is curious that some of these formations develop rapidly without associated pain, whereas others can cause persistent pain and lameness for many weeks, despite a similar radiological appearance. The bony protuberances that develop on the proximolateral aspect of the metatarsal regions, often bilaterally, are even more enigmatic. They are rarely associated with clinical signs, although they often have IRU despite having been present for several years.

Endosteal New Bone

Endosteal new bone may develop as a result of trauma (e.g., a cortical or subcortical fracture or trauma at an enthesis) or inflammation, infection, or, less commonly, a tumor (Figure 15-2). Stress fractures of the dorsal cortex of the McIII are accompanied by the development of endosteal new bone, which may be more readily detected than the fracture itself.

Fig. 15-2 • Lateromedial radiographic image of the proximal tibia. There is increased opacity of the subcortical bone of the proximocaudal aspect of the tibia. Endosteal new bone (arrows) is associated with a fatigue (stress) fracture.

Sclerosis

Sclerosis is the localized formation of new bone within bone and results in increased bone mass. It is most easily identified in trabecular bone (Figure 15-3) and occurs in response to several stimuli, including the following:

- Stress (e.g., subchondral sclerosis in osteoarthritis and sclerosis of the medulla of the navicular bone in navicular disease)
- Protection of a weakened area (e.g., sclerosis surrounding an osseous cystlike lesion or a subchondral bone cyst)
- Walling off infection (e.g., adjacent to a sequestrum or in the medullary cavity adjacent to an area of osteomyelitis)

Enostosis-like lesions are the development of bone within the medullary cavity or on the endosteum, resulting in a relatively opaque (sclerotic) area of variable size. They frequently occur adjacent to the nutrient foramen, and the origin is unclear. They may develop as a focal or multifocal lesion. They vary in size and generally are seen in the diaphyseal regions of long bones in the horse. These lesions have been seen most frequently in the humerus, the radius, the tibia, the McIII, the third metatarsal bones, and the femur. When these lesions develop, they have focal intense IRU and may be associated with pain and lameness. However, they also are seen as incidental findings.

Small focal opacities in the proximal metaphyseal region of the tibia have been seen. The origin and clinical significance are not known. Care must be taken in the fetlock region not to misinterpret the radiopacity caused by the ergot as an opaque lesion within the proximal phalanx.

Osteophyte Formation

An osteophyte is a spur of bone on a joint margin that develops as a result of a variety of stimuli, including joint instability, or in association with intraarticular disease, particularly osteoarthritis. Not all periarticular modeling changes at the junction of the articular cartilage and periarticular bone are associated with ongoing joint disease, but radiological differentiation between a subclinical osteophyte and a clinically significant one is difficult. Small spurs frequently are seen on the dorsoproximal aspect of the third metatarsal bone close to the tarsometatarsal joint. Some are quiescent, unassociated with articular pathological findings, whereas others are progressive. Small spurs on

Fig. 15-3 • Palmaroproximal-palmarodistal oblique radiographic image of a navicular bone. The flexor cortex is thickened, and there is extensive endosteal new bone (arrows) resulting in increased radiopacity of the spongiosa.

Fig. 15-4 • Lateromedial radiographic image of a hock. There is a moderately sized periarticular osteophyte on the dorsoproximal aspect of the third metatarsal bone, close to and traversing the tarsometatarsal joint (arrow).

the dorsoproximal aspect of the middle phalanx are frequent incidental findings in Warmblood breeds. Mature horses with offset- or bench-knee conformation frequently have spurs on the lateral aspect of the antebrachiocarpal joint without associated clinical signs.

The time of development of an osteophyte after stimulus varies depending on the inciting cause and individual variation. Two weeks to several months may pass before an osteophyte may be identified radiologically. A smoothly margined osteophyte of uniform opacity is more likely to be long-standing, whereas a poorly margined osteophyte with a lucent tip is likely to be active.

Some joints seem to have a greater propensity than others for the development of periarticular osteophyte formation. The reason for this tendency is unknown and may in part reflect the ease with which osteophytes can be detected radiologically. Even within what is currently considered a single disease process, osteoarthritis of the distal hock joints (bone spavin), some horses develop predominantly periarticular osteophytes (Figure 15-4), whereas others have narrowing of the joint space and subchondral sclerosis. A third group develops extensive radiolucent areas (Figure 15-5).

Enthesophyte Formation

Enthesophyte formation is new bone at the site of attachment of a tendon, ligament, or joint capsule to bone. Entheseous new bone reflects the bone's response to stress applied through these structures, such as ligamentous tearing or capsular traction (Figure 15-6). Like osteophytes, enthesophyte formations take several weeks to months to develop and may or may not be associated with clinical signs. Knowledge of ligament, tendon, and capsular insertions is essential to determine which soft tissue structure

Fig. 15-5 • Dorsolateral-plantaromedial oblique radiographic image of a hock. There is narrowing of the centrodistal joint space. Radiolucent regions are seen in the subchondral bone of the central and third tarsal bones dorsomedially. There is loss of trabecular architecture because of medullary increased radiopacity in the central and third tarsal bones. Note also the osseous cystlike lesion in the distal dorsomedial aspect of the third tarsal bone.

Fig. 15-6 • Dorsolateral-palmaromedial oblique radiographic image of a pastern. There is enthesiophyte new bone (arrow) on the middiaphyseal region of the proximal phalanx at the site of insertion of the oblique sesamoidean ligament. There is enthesiophyte new bone further distally (arrow-head) at the origin of the ligament between the proximal phalanx and the cartilage of the foot, the chondrocompedal ligament.

may have been damaged. In some locations, such as the hock, differentiation between enthesophyte and osteophyte formation is not easy. The attachments of the cranialis tibialis, fibularis tertius, and dorsal tarsal ligament are close to the joint margins of the tarsometatarsal joint, and differentiation between enthesiophyte formation at these attachments and periarticular osteophyte formation may be difficult. Entheseous new bone may take the form of spur formation, such as at the site of attachment of the common digital extensor tendon on the distal phalanx or the site of attachment of the oblique sesamoidean ligament on the palmar aspect of the proximal phalanx. At other sites, such as the origin of the suspensory ligament (SL) on the plantar aspect of the third metatarsal bone, new bone formation may be more diffuse. Diffuse new bone formation on the caudal aspect of the occiput reflects tearing of the attachment of the nuchal ligament. New bone on the

dorsal aspect of the radial, intermediate, ulnar, or third carpal bones may reflect enthesseous new bone at the site of attachment of intercarpal ligaments or the joint capsule. Such new bone does not necessarily reflect osteoarthritis, but it may reflect slight joint instability, which itself may predispose to the development of osteoarthritis. Similarly, joint trauma resulting in sprain of periarticular ligaments and subsequent enthesseous new bone may ultimately also result in osteoarthritis.

Fracture of an enthesophyte and mineralization within the tendon or ligament attachment also may occur. A relatively common site is the radial tuberosity at the attachment of biceps brachii. Small linear opacities may be seen dorsal to the summits of the spinous processes in the thoracic region, which are associated with tearing of the attachment of the supraspinous ligament.

Spondylosis

Ossifying spondylosis occurs in the caudal half of the thoracic region in the horse. Spondyles (osteophytes) arise from the ventral aspect of the vertebral bodies near the intercentral articulations. The osteophytes extend across the intercentral articulation toward similar osteophytes on adjacent vertebrae. Usually a lucent line persists between the two spondyles, although sometimes complete bridging does occur. Spondylosis may be progressive in cranial and caudal directions, although in some horses it remains static.

New Bone of Unknown Origin

New bone sometimes develops on the dorsal aspect of the diaphysis and distal metaphyseal region of the middle phalanx. The cause of this is unknown. It may be asymptomatic.

Hypertrophic Osteopathy

Hypertrophic osteopathy (Marie's disease) is typified by palisading periosteal new bone, which appears to be perpendicular to the cortices and irregular in outline in the acute stage. It affects principally the diaphyseal and metaphyseal regions of long bones and spares the joints. In the early stages, very soft exposures must be used to avoid overexposing this relatively radiolucent bone. Later the margins of the new bone become more opaque and smoother, and the distinction between the original cortex and the new bone becomes less obvious. These bony lesions develop secondary to a tumor, abscess, or other lesion in the thorax or abdomen, or in association with diffuse granulomatous disease. The bony lesions may regress and model if the primary lesion can be identified and successfully treated.

Osteitis

Osteitis is inflammation of bone. It may be noninfectious or infectious. Noninfectious osteitis usually is the result of trauma or inflammation of the adjacent soft tissues. It is characterized by new bone formation and, less commonly, bone resorption.

Infectious Osteitis and Osteomyelitis

Infectious osteitis is inflammation of bone as a result of infection. In bones with a myeloid cavity the term *osteomyelitis* is used if the myeloid cavity is affected. Infection

Fig. 15-7 • Dorsomedial-palmarolateral radiographic image of a metacarpal region of a 5-year-old Warmblood that had been kicked 2 months earlier. There is soft tissue swelling overlying ill-defined periosteal new bone. There is a radiolucent defect in the lateral cortex of the third metacarpal bone with an acentric, more radiolucent area. These abnormalities are consistent with infectious osteitis.

results in soft tissue swelling, new bone formation, and bone resorption. In the distal phalanx and the distal sesamoid (navicular) bone, bone lysis predominates with little new bone formation. In other bones a combination of loss of bone and new bone formation usually occurs. A piece of dead radiopaque bone, or a sequestrum, may develop, surrounded by an area of lucent granulation tissue, the involucrum (Figure 15-7). An area of more radiopaque bone may be laid down surrounding the infected area to wall off infection. A radiolucent tract, a sinus, may develop between the infected tissues and the skin. In the early stages, diagnostic ultrasonography may be more sensitive than radiography for detecting infection.

Osseous Cystlike Lesions and Subchondral Bone Cysts

Osseous cystlike lesions are solitary, circular, or semicircular lucent areas in a bone; they usually develop in the subchondral bone. Sometimes a neck can be identified connecting the cyst to the joint cavity. Cystlike lesions may be unicameral (single chambered) or, less commonly, multicameral. A sclerotic rim frequently surrounds osseous cystlike lesions. Those that develop before skeletal maturity often appear to migrate away from the joint surface as normal endochondral ossification occurs. These single osseous cystlike lesions, which are not associated with any pathological changes in the articular cartilage, should be differentiated from the more poorly defined lucent zones that develop in the subchondral bone in osteochondrosis.

The cause of osseous cystlike lesions is probably multifactorial. Some are true subchondral bone cysts and have

a fibrous cystic lining. There is increasing evidence that some of these lesions develop as a response to trauma to the articular cartilage and subchondral bone. They tend to occur most commonly in the medial condyle of the femur and in the center of the glenoid cavity of the scapula. Other osseous cystlike lesions may have a different histological appearance, despite similar radiological appearance. Osseous cystlike lesions in the proximal medial aspect of the radius tend to be associated with periosteal new bone in the region of insertion of the medial collateral ligament. Other common locations include the distal aspect of the McIII and the proximal, distal, and middle phalanges.

Care should be taken when evaluating some bones, especially the phalanges, not to confuse the myeloid cavity with an osseous cystlike lesion.

The development of some osseous cystlike lesions can be followed radiologically. Some start as a small, elliptical depression in the articular surface that progressively enlarges into the subchondral bone. A sclerotic margin develops.

Osseous cystlike lesions may be associated with lameness. Lesions deep in the bone, such as those seen in the first, second, and ulnar carpal bones, are rarely associated with lameness. Cystlike lesions that are close to an articular surface are more likely to be associated with lameness. However, the lameness may be remarkable in its variable nature and severity. Lameness may resolve spontaneously or after surgical intervention, despite persistence of a lesion, radiologically.

The incidence of the development of osseous cystlike lesions is higher in young horses than older horses. Some horses develop a subchondral bone cyst early in life that remains clinically quiescent, only to cause clinical signs later in life. However, subchondral bone cysts and osseous cystlike lesions can develop in skeletally mature horses.

It can be difficult to determine the likely clinical significance of a subchondral bone cyst or an osseous cystlike lesion based purely on radiological appearance. Scintigraphic evaluation may be helpful, because many have IRU, but it can also be confusing because a long-established cystlike lesion that has been clinically quiescent can suddenly become a source of pain without evidence of active bone modeling. It is always important to evaluate radiologically the joint in its entirety, because evidence of secondary osteoarthritis warrants a more guarded prognosis.

Osteochondrosis

Osteochondrosis is considered a disorder of endochondral ossification, although there is increasing evidence that primary subchondral bone lesions also may occur. Osteochondrosis can cause osseous cystlike lesions and osteochondritis dissecans. Osteochondritis dissecans may be generalized although it is evident clinically and radiologically only in certain joints. The femoropatellar, tarsocrural, fetlock, and scapulohumeral joints are most commonly affected. Radiological abnormalities vary depending on the joint involved and include the following:

- Discrete osteochondral fragments
- Flattening or depression in the articular surface
- Subchondral lucent zones
- Increased radiopacity in the subchondral bone, surrounding lucent zones, or parallel with the joint surface
- Secondary osteoarthritis

Fig. 15-8 • Caudolateral-craniomedial oblique radiographic image of a stifle of an 8-year-old Warmblood show jumper with no history of lameness, undergoing a prepurchase examination. There is a concave depression in the middle of the lateral trochlea of the femur, with mild subchondral increased radiopacity and ill-defined lucent areas. In addition, there are one large and several small radiopaque bodies visible in the concave depression. This is osteochondrosis.

Radiological changes are not always clinically significant but must be interpreted in the light of clinical signs. Flattening of contour of the lateral trochlear ridge of the femur, with sclerosis of the subchondral bone, may be seen in the absence of lameness in mature horses. However, identical changes may be present in horses with poor hindlimb action referable to pain associated with the femoropatellar joints (Figure 15-8). Flattening of contour or the presence of elliptical depressions in the trochleas of the talus with normal subchondral bone opacity is rarely associated with clinical signs. The more change in the subchondral bone, the more likely that clinical signs will be present. Small osteochondral fragments may become lodged in the synovial membrane and become progressively larger. Trauma may result in such lesions becoming dislodged and mobile and result in clinical signs.

FRACTURE

A fracture is a discontinuity of bone that may be seen radiologically as one or more lucent lines. Mach lines, or bands, should not be confused with a fracture. A Mach line or band is a radiolucent line created by edge enhancement when one bone edge is superimposed over another bone. Superimposition of the second and fourth metacarpal bones on the McIII commonly results in Mach lines. In a caudocranial view of the proximal tibia, a Mach line is created by superimposition of the tibial crest on the tibia.

Large exostoses involving the second or fourth metacarpal bone or fourth metacarpal or fourth metatarsal bone often result in confusing lucent lines, apparently within

the bone, which must not be interpreted as fractures. Likewise, some bony exostoses in these locations incorporate some fibrous tissue, resulting in a persistent lucent line that should not be confused with a fracture. A nutrient foramen that traverses a bone should also not be interpreted as fracture. Most nutrient foramina are broader than a recent fracture would be expected to be. A notable exception is the vertically orientated nutrient foramen in the second metacarpal or second metatarsal bone and the fourth metacarpal or fourth metatarsal bone. It is important not to misinterpret lucent lines in the foot created by the frog clefts as fracture lines. Despite careful packing of the frog clefts and sulcus (with, for example, Play-Doh), complete packing is impossible if these are very deep and will result in narrow lucent lines. Care should be taken to see if such a lucent line (e.g., apparently in the navicular bone) extends beyond the bone margins. If the angle of projection is altered slightly, does the position of the line change relative to the medial and lateral borders of the bone? Can the same lucent line be seen in a dorsopalmar image? Care must also be taken not to confuse the lucent bands between separate centers of ossification with fracture lines. The cartilages of the foot and the fibula frequently develop as separate centers of ossification, and bony union may never develop between the different ossification centers, which results in lucent gaps within each bone that persist over the long term. A long, thick hair coat that is wet sometimes can result in the appearance of a lucent line or lines superimposed over bone, which must not be interpreted as a fracture.

Some stress or fatigue fractures are never detectable radiologically. Some can be seen as one or more lucent lines, or, if fractures are chronic, there may be endosteal new bone or increased medullary opacity. If a chronic stress fracture traverses a cortex, there may be periosteal callus, although the fracture line itself may not be detectable.

Ideally, the postulated radiolucent fracture line should be detectable on more than one radiographic image to confirm the presence of a fracture. However, this is not always possible, especially if the fracture is incomplete and nondisplaced. This is particularly true for fractures of the distal phalanx and incomplete dorsal cortical fractures of the proximal phalanx. For best results, the x-ray beam must be perpendicular to the plane of the fracture line. Many different views that differ by only 5 degrees in angle of projection may be required for detection of a fissure fracture. With a complete fracture, many different views may be required for determination of the precise configuration of the fracture.

Some fractures are not detectable in the standard radiographic images of the area under examination. A fracture of the lateral palmar process of the distal phalanx may not be detectable in lateromedial, dorsopalmar, and dorsoproximal-palmarodistal oblique images. Dorsolateral-palmaromedial oblique or sometimes a palmaroproximal-palmarodistal oblique image, or a dorsal 60° proximal 45° lateral-palmarodistal medial oblique view, is required. Sagittal and some slab fractures of the third carpal bone are visible only in dorsoproximal-dorsodistal oblique images of the flexed carpus (the skyline projection). Similarly, fractures of the medial pole of the patella are only detectable in cranioproximal-craniodistal oblique images of the flexed stifle.

The normal healing process of a fracture involves osteoclasts along the fracture line within 5 to 10 days, resulting in initial broadening of the fracture line. Therefore if a fracture is suspected but cannot be seen in the acute stage, radiography should be repeated after 5 to 10 days. Care should be taken not to underexpose the radiograph, because a faint lucent line may be missed. Paradoxically, early callus formation, which develops within 14 to 21 days, will be missed if the radiograph is overexposed or not viewed over high-intensity illumination or if a computer screen is viewed in excessively bright light.

A fracture should be evaluated to determine whether it is complete or incomplete and simple or comminuted, whether fracture fragments are displaced, whether articular involvement is present, and whether any other concurrent pathological condition is present that may influence the prognosis. An apical proximal sesamoid bone fracture may be accompanied by severe desmitis of the branch of the SL, which prognostically is the more severe injury. Biaxial transverse fractures of the proximal sesamoid bones result in disruption of the suspensory apparatus and severe risk of compromising the blood supply to the distal part of the limb. An avulsion fracture of the proximal phalanx at the attachment of the lateral collateral ligament of the metacarpophalangeal joint will result in loss of joint stability.

It is important to be aware that with a single, complete fracture, two lucent lines representing the fracture traversing, for example, the dorsal and palmar cortices, may be seen. These lines should not be confused with two fractures. However, care must always be taken to make sure that there is not more than a single fracture line. For example, a common fracture in steeplechasers that fall is a vertical fracture through the body of the accessory carpal bone. These horses have a good prognosis with conservative management. Rarely, one or more chip fractures involving the articular margins of the bone occur; such injuries warrant a much more guarded prognosis. An event horse that hits a fixed fence during cross-country jumping may fracture the medial trochlear ridge of the femur. Fracture fragments may readily be seen in a lateromedial image of the stifle. Such fractures also can be accompanied by a fracture of the medial pole of the patella, which can be seen only in a skyline image. Therefore it is essential to obtain a complete radiographic series and interpret each radiograph in its entirety.

Intraarticular fractures occur when a break in the articular surface occurs. Unless some degree of displacement is present, damage to the articular cartilage may not be seen but is assumed to exist. A small degree of displacement is indicated by the presence of a slight step in the two sides of the articular portion of the fracture line. Comminution at the joint surface sometimes occurs. This may not be evident in standard radiographic images. For example, lateral condylar fractures of the McIII may be accompanied by a Y fragment at the articular margin that is detectable only in dorsodistal-palmaroproximal oblique images.

Fractures on an articular margin are called *chip fractures*. In some locations, such as the antebrachiocarpal and middle carpal joints, it is important to assess the radiographs carefully for evidence of preexisting osteoarthritis, which would have predisposed to the fracture and may influence the prognosis. The veterinarian should bear in mind that more than one chip may exist.

Chip fractures of the articular margins should be differentiated where possible from separate centers of ossification, avulsion fractures that occurred in the neonatal period, and ectopic mineralization. The position of the mineralized body relative to the articular margin, the size and shape of the body, and the contour of the articular margin should all be assessed carefully. A recent chip fracture may have a sharp edge, and a detectable fracture bed from which it originated may be seen. Separate centers of ossification usually are well rounded and uniformly opaque with no discernible fracture bed. It is important to recognize that such pieces may be clinically silent, but some are associated with lameness. The clinical significance must be interpreted in the light of clinical signs and the response to diagnostic analgesia. Ectopic mineralization may be present within the joint capsule.

Osteochondral fragments, the result of osteochondritis dissecans, should not be confused with a fracture. Osseous fragments may be seen, for instance, distal to the trochleas of the talus at the entrance to the talocalcaneal-centroquarantal (proximal intertarsal) joint. These fragments may have originated from the distal (cranial) aspect of the intermediate ridge of the tibia and usually are of no clinical significance. Well-rounded, smoothly margined osseous opacities may be seen on the proximoplantar aspect of the proximal phalanx. These may be the result of avulsion fractures of the short, deep cruciate sesamoidean ligaments that were sustained early in life; they are not always clinically significant but may compromise performance at maximum levels. The variably present first and fifth carpal bones should not be mistaken for fractures.

In some joints, it may not be possible to determine radiologically the origin of a fracture fragment. For example, fragments in the femorotibial joint frequently are not associated with any detectable disruption in bone outlines, and only arthroscopic evaluation of the joint allows determination of the origin. It also may not be possible to determine whether an accompanying soft tissue pathological condition exists. A fracture of the medial intercondylar eminence of the tibia may occur alone. The prognosis is good with surgical removal. Sometimes, however, concurrent cranial cruciate ligament damage exists at its insertion cranial to the eminence, resulting in a much more guarded prognosis.

A slab fracture is a fracture that extends from one joint surface to another (e.g., from the proximal to the distal aspect of the third carpal bone or central or third tarsal bones). These fractures can be extremely difficult to detect in the acute stage if not displaced.

In some locations, determination of the origin of a fracture fragment is facilitated by ultrasonographic examination. For example, a fragment on the palmar aspect of the fetlock may be an avulsion fracture of the insertion of the palmar annular ligament on the proximal sesamoid bone, and this is readily confirmed ultrasonographically.

Fracture healing depends on many factors, including the age of the horse, its nutritional and metabolic status, the site and stability of the fracture, the presence or absence of periosteum or infection, and the blood supply to the bone. After initial mineral resorption along the fracture line and formation of fibrous callus, calcified periosteal and endosteal callus develop. The amount and quality of callus that develops depends on the degree of stability at the

fracture site and the presence or absence of infection. If a fracture is stable, either because it is incomplete or because it has been stabilized by internal fixation, healing is predominantly by primary union and endosteal reaction with minimal periosteal callus. Instability results in the development of periosteal callus.

The fracture may become stable long before the fracture line disappears radiologically. Healing may be complete within 6 to 12 weeks, with progressive narrowing and ultimate disappearance of the fracture line. However, healing of some fractures takes considerably longer. A horse may be sound and able to withstand full work despite the persistence of a radiolucent fracture line. In some locations (e.g., lateral condylar fractures of the McIII) a persistent lucent line may be associated with recurrent and persistent pain.

Some bones tend to heal by fibrous union, resulting in a persistent lucent line. These include the accessory carpal bone, the proximal and distal sesamoid bones, and the distal phalanx. Unless a fracture of the navicular bone is stabilized by internal fixation, lucent areas tend to develop in the adjacent bone along the fracture line. These indicate a chronic fracture of the navicular bone of at least 6 to 8 weeks' duration.

If a fracture line persists beyond 6 months, it can be considered to be a delayed union. Sclerosis of the bone adjacent to the fracture line may be present, and the ends of the bone may be slightly flared. Delayed union is not uncommon, but nonunion is unusual in the horse except in those bones that tend to heal by fibrous union.

Aging of a fracture is not easy to determine radiologically with any accuracy. The presence of periosteal callus (Figure 15-9) indicates a fracture of at least 14 days' duration and often substantially longer. An acute fracture has very clearly

Fig. 15-9 • Craniolateral-caudomedial oblique radiographic image of the proximal aspect of the tibia of a 3-year-old Thoroughbred filly. Periosteal callus formation (arrows) on the caudoproximal aspect of the tibia is associated with a stress fracture. The oblique lucent line in the proximal aspect of the tibia is a nutrient foramen.

defined margins, which become less distinct as resorption occurs along the fracture line during early healing.

DEGENERATIVE JOINT DISEASE: OSTEOARTHRITIS OR OSTEOARTHRITIS

Arthritis means inflammation of a joint. The term *osteoarthritis* or *osteoarthrosis* indicates that bone has become involved and that a soft tissue component may (*-itis*) or may not (*-osis*) be present. The term *secondary joint disease* sometimes is used to denote that the degenerative changes are secondary to a known condition, such as infection or osteochondrosis. Any condition that damages cartilage, causes joint instability, or places abnormal forces on the joint may result in osteoarthritis. It may develop as a result of abnormal conformation or be the result of wear and tear on an athletic horse. However, advanced osteoarthritis sometimes is seen in relatively young horses with no identifiable predisposing cause.

Radiological abnormalities associated with osteoarthritis include the following:

- Periarticular osteophyte formation
- Narrowing of the joint space
- Subchondral lucent zones, either well or poorly defined
- Increased subchondral bone opacity (sclerosis); loss of trabecular pattern
- Thickening of the subchondral bone plate
- Joint capsule distention

However, it is important to recognize that in some joints advanced osteoarthritis may be present without any detectable radiological change. Periarticular osteophytes are not necessarily synonymous with clinically significant osteoarthritis. It is relatively unusual to see subchondral lucent zones in high-motion joints. These occur more commonly in the low-motion joints, such as the distal hock and proximal interphalangeal joints.

A relatively poor correlation exists between the degree of radiological change associated with osteoarthritis and the degree of pain and thus lameness. Advanced radiological change may be present when lameness is first recognized, which clearly must have predated the onset of recognizable clinical signs. In contrast, obvious lameness associated with joint pain may be present without detectable radiological change. Widespread wear lines may be present on the articular cartilage without associated radiological change.

Therefore dating the likely onset of clinical signs based on the radiological appearance of a joint can be difficult. It also can be difficult to predict the likely progression of minor radiological changes, such as small periarticular osteophytes, which may be present without clinical signs at, for example, a prepurchase examination.

LUXATION AND SUBLUXATION

Luxation is the complete loss of contact between articular surfaces. Subluxation is partial loss of contact between joint surfaces and may be intermittent. Both are usually the result of trauma, although congenital luxation of the patella occurs occasionally. Subluxation of the proximal

interphalangeal joint may occur without any obvious cause, especially in hindlimbs. Subluxation is easy to identify radiologically, but the radiographs must be evaluated carefully to identify any concurrent fracture that will adversely influence prognosis.

Subluxation may not be obvious radiologically, and stress radiographs obtained with the limb not bearing weight, with pressure applied in a mediolateral or dorso-palmar direction, may be necessary to determine if the bones can be moved relative to each other.

DYSTROPHIC AND METASTATIC MINERALIZATION

Soft tissue mineralization is classified as metastatic or dystrophic. Metastatic mineralization is the deposition of mineral in normal tissues and is associated with hypercalcemia, hyperphosphatemia, or hypercalciuria and is unusual in the horse. Dystrophic mineralization is the deposition of mineral in injured, degenerating, or necrotic tissue and occurs quite commonly in the horse in, for example, a damaged SL. It can occur secondary to any injury to soft tissue subsequent to infarction, hemorrhage, or inflammation. Dystrophic mineralization may ultimately become ossified.

RADIOGRAPHIC EXAMINATION

For each joint or region to be examined there is a standard radiographic technique that includes a basic minimum number of views for routine evaluation of the region. This usually includes a minimum of four images for joints distal to the elbow and stifle. However, radiographic technique must be flexible. For example, if a fracture is suspected, various images differing only slightly in angle of projection may be required. Some fractures are visible only on special projections. For example, a fracture of the medial pole of the patella may be detected only in a cranioproximal-craniodistal oblique image. Exposure factors need to be altered depending on the size of the horse and the area being evaluated. Exposure factors ideal for assessing trabecular structure within medullary bone result in overexposure of immature periosteal new bone. Underexposure may result in a fracture line or alterations in corticomedullary demarcation and trabecular structure being missed.

It is also important to realize how position sensitive some radiological abnormalities are and how easily artifacts can be created. For example, the accurate evaluation of corticomedullary demarcation and trabecular structure within the navicular bone in a palmaroproximal-palmarodistal oblique image depends highly on the position of the limb and the angle of the x-ray beam. The optimum angle of the x-ray beam depends on the shape of the foot. Inappropriate positioning of the foot or use of an x-ray beam that is not tangential to the flexor surface of the navicular bone will result in artifacts.

The x-ray beam should be coned down on the area of interest as much as possible and centered on the area of interest. Lesions will be missed if an attempt is made to evaluate too much in a single image (e.g., the fetlock, pastern, and foot). It frequently is helpful to obtain

comparative images of the contralateral limb. These should be obtained with identical exposure factors and similar positioning of the limb and angulation of the x-ray beam for accurate evaluation. Comparison of radiographs with a known normal example of similar age can also be helpful. It is thus useful to compile an image library of normal examples.

INTERPRETING RADIOGRAPHS

Radiographs should be evaluated in a systematic way. First, the quality of the radiographs should be assessed. Is the horse positioned appropriately? Are the radiographs of adequate quality? Are there any artifacts? The films should be viewed on a proper viewing box, both close to and from far away. The veterinarian should view the films under both normal and high-intensity illuminations, should interpret the entire film, and should follow all the bone margins and then evaluate the internal architecture. For computed or digital radiography the computer screen should be of high resolution and should be viewed in low-intensity light. The image should be windowed if necessary (i.e., alteration of brightness and contrast). The veterinarian should avoid lesion or disease spotting but aim to describe the radiological abnormalities and then deduce potential causes of the abnormality.

If a lesion is suspected but further information is required, the clinician should consider coning down, altering the exposure factors, slightly changing the angle of projection, or using special views. The radiographs should be compared with normal bone specimens, with an awareness that not all radiological abnormalities are necessarily of clinical significance. Knowledge of normal anatomy and normal variations is essential, together with knowledge of the sites of ligament, tendon, and joint capsule insertions.^{1,2} Recognition of breed differences also is important.

Radiological abnormalities must be interpreted in the light of clinical signs. It is also important to recognize that there are discipline differences in the potential clinical significance of some lesions. For example, mild osteoarthritis in the antebrachiocarpal or middle carpal joint may compromise the performance and career of a flat racehorse but be of little clinical significance for a show horse or low-level show jumper. It must also be recognized that it is often not possible to predict the future development of lesions. A horse with a small osteophyte on the dorsoproximal aspect of the third metatarsal bone may look identical in a later year, but a different horse may have developed extensive periarticular osteophytes involving both the centrodistal and tarsometatarsal joints.

Determining the Age of a Lesion

It is often not possible to accurately determine the age of a lesion that is identified radiologically. Periosteal new bone usually takes at least 14 days to be visible radiologically after trauma. Once new bone is well consolidated and smoothly margined, it is impossible to determine how long it might have been present. A nondisplaced fracture may take up to 10 days to become evident radiologically; loss of clarity of the fracture margins may indicate that it has been present longer. Radiological changes compatible with osteoarthritis can precede the onset of clinical signs and may be relatively advanced when lameness is first recognized. It is not possible to determine when the changes first developed.

RADIOGRAPHIC TECHNIQUE

Standard radiographic projections are outlined in [Table 15-1](#). For detailed descriptions of radiographic technique for all regions of the musculoskeletal system, readers are

referred to *Clinical Radiology of the Horse*.³ Throughout this text, radiographic images are described using the technique advocated by the American College of Veterinary Radiology.⁴

All radiographs should be permanently labeled photographically on the film, by use of special tape attached to the cassette when the film is exposed, a labeling light box system in the darkroom, or a computer. Labels should include at least the identity of the horse, the date, the limb examined, and medial or lateral when appropriate. The following facts also are preferable on the label: the name of the owner or agent of the horse, the name of the veterinary practice, and the identity of the view (e.g., PaL-DMO). For ease of identification, it can be helpful if the horse's label is always positioned on the lateral aspect of the cassette or imaging plate; if a medial marker were omitted, it would then still be possible to differentiate between the medial and lateral sides.

Radiographs are part of the horse's permanent medical and legal record and should always be retained by the

veterinary practice for future reference unless the owner of the horse gives permission for the radiographs to be transferred to another veterinary practice. Electronic or copy radiographs are easily produced if a client wishes to have his or her own copy.

Digital radiography generally uses imaging plates with a larger exposure latitude compared with traditional film-screen combinations. Therefore it is potentially easier to obtain good-quality images with a single exposure. With a computerized system the images can be manipulated to enhance contrast and magnify areas of interest; therefore lesions that might previously have been missed may be more readily identified. With an appropriate archiving system, all images can be stored digitally rather than printed. It is crucial that an adequate backup system be in place to protect against data loss. Digital radiography is not a substitute for good radiographic technique but offers the advantage of providing images that may be of superior quality and can be stored and transmitted electronically.

Chapter 16

Ultrasonographic Evaluation of the Equine Limb: Technique

Norman W. Rantanen, Joan S. Jorgensen, and Ronald L. Genovese

Diagnostic ultrasonography was introduced in the early 1980s as a practical imaging modality to evaluate soft tissue injuries of the equine limb.¹ It continues to be used extensively for evaluation of tendinous and ligamentous structures to identify, confirm, and monitor soft tissue injury (Box 16-1).²⁻⁸ Ultrasonography is now the imaging modality of choice for most soft tissue evaluation, but in the digit magnetic resonance imaging (MRI), if available, is most

useful to evaluate soft tissues. However, it is user specific, and diagnostic information relies heavily on adequate equipment, limb preparation, and the scanning skills of the ultrasonographer. This chapter describes terminology and techniques and provides advice about interpretation based on our collective experiences. We describe our systematic approach, which includes both qualitative and quantitative ultrasonographic analysis of distal limb injuries. The resulting data can be used to categorize the severity of the injury and compare with subsequent examinations. The technology is still developing, and changes will evolve to improve the clinician's ability to identify and substantiate clinical findings, leading to improved management of soft tissue injury in the horse.

EQUIPMENT

Ultrasound machines used for musculoskeletal imaging require a range of transducer frequencies to examine superficial and deep structures. Soft tissues within 5 to 7 cm of the skin surface should be examined using a transducer with a frequency of at least 7.5 MHz or higher. Tissues within 7 to 15 cm of the skin surface are best evaluated with a 5.0-MHz transducer, whereas deeper tissues require a transducer in the 2.5- to 3.5-MHz range.

Sound is attenuated at 1 dB/cm depth per megahertz. Higher frequencies are attenuated at higher rates, thus limiting penetration. Conversely, lower frequencies, attenuated at lower rates, have greater penetration. The highest frequency possible should be used to obtain maximum resolution.

Claiming that one instrument is the only one to perform musculoskeletal examination is naive at best and totally inaccurate. All state-of-the-art machines have similar focusing capabilities and resolving power. Image appearances made by different machines at the same frequencies have subtle differences; however, resolution is about the

BOX 16-1

Indications for Ultrasonographic Evaluation of Limbs

- Diagnosis of soft tissue injuries, including muscular, vascular, tendon, tendon sheath, ligament, joint capsule, or bursal defects
- Assessment of fluid accumulation
- Evaluation of bony surfaces
- Monitoring of the healing progress
- Monitoring of the effect of training on soft tissue structures, especially tendons and ligaments

same. Images may appear more crisp from transducers with a greater number of elements. Operator proficiency (or lack of it) largely determines image quality.

Large muscle masses or bone surfaces, such as the pelvis, are more effectively scanned with phased array, convex array, annular array, or sector transducers. The small skin surface imprints and divergent beam are advantageous when tissues are imaged at greater depths. However, annular array and sector transducers have focal zones that usually favor the central portion of the beam and have beam divergence, which causes far-field, lateral beam width artifact. Convex and phased array transducers have electronic focusing, and the examiner can control focal zone number and placement. It is common for these transducers to penetrate up to 30 cm.

Linear array transducers are the most popular for tendon and ligament scanning because they facilitate anatomical recognition of structures and evaluation of longitudinal tendon and ligament fiber alignment parallel to the skin surface. Convex array and sector transducers, if used properly, work equally well. However, they are more difficult to use because it is easier to change the beam direction because of the smaller contact area. It is necessary to keep the beam at 90 degrees to the tendon or ligament fibers. Anatomical features may be more difficult to recognize. Standoff pads are essential with any transducer to image the most superficial structures.

Sector and microconvex array transducers are preferable for use on contoured skin surfaces. For instance, scanning between the heel bulbs is difficult with a flat-face, linear array transducer but simple with convex or sector transducers. It is easier to steer a divergent beam and look around from a smaller contact area compared with the flat-face, linear array transducer's broad contact area and rectangular sound beam.

Multiple frequency scanheads are available from most manufacturers; these scanheads allow operators to change frequencies relative to tissue depths without changing transducers. Newer broadband scanhead technology ensures quality, and there are no disadvantages in using these scanheads for musculoskeletal scanning, provided that basic ultrasound principles are practiced.

HORSE PREPARATION

The horse should be adequately restrained, because an anxious, fidgety horse may cause a hurried or inadequate examination, resulting in poor-quality images and interpretive errors. One author (RLG) prefers to sedate most horses that are not entered in drug-tested competition to ensure that the horse stands quietly during the examination. The horse should be held by a person who has responsibility for the safety of the ultrasonographer and the equipment. A calm, well-positioned horse allows a thorough, tension-free evaluation.

Hair, air, scurf, scabs, and dirt induce artifacts and reduce image quality. The hair should be clipped with a No. 40 or No. 50 blade then cleaned with an antiseptic scrub, followed by a generous rinse with water, taking care to follow the growth pattern of the hair. In some horses an additional close shave with a disposable razor may improve image quality. Acoustic coupling gel is applied to improve transducer contact. Excessive application of gel

causes a lateral image artifact that may impair assessment of the structures being examined, especially if peritendinous or periligamentous neural, vascular, and connective tissue structures are being evaluated. Removal of the excess gel from the transducer head or the limb corrects the artifact.

If the hair coat is fine and clipping or shaving is not possible or desired, then the limb can be washed. The examiner should spend some time wetting and soaking the hair to improve transducer contact. Topical application of alcohol while stroking the hair along its growth path may improve transducer contact,⁵ but *alcohol can be harmful to some transducers*. The operator should contact the manufacturer of the equipment to ensure that it is safe to use the transducer with alcohol.

MEDICAL RECORDS

Ultrasonographic images should be recorded using thermal prints, video recording, or digital recording. Thermal images were used most commonly in the past, but digital recording is rapidly superseding them.

Thermal Print Storage Envelope

Practical hints and suggestions for medical record documentation that can simplify case records, enhance clinical information for serial studies, and improve documentation are provided in the following text. We recommend a simple form stamped on the outside of a storage envelope. The information on the envelopes can be quickly filled in using symbols or checkmarks and should include the following data: horse identification, date, owner, trainer, limb or limbs examined, and structure or structures evaluated (superficial digital flexor tendon [SDFT], deep digital flexor tendon [DDFT], accessory ligament of the DDFT [ALDDFT], main body of the suspensory ligament [SL], SL branch, pastern, hock, antebrachium, crus, and other). It is also useful to record exercise level, the reason the examination was performed, and a brief summary of clinical findings. This checklist indicates which structures have been targeted and assists in interpretation of an actual lesion versus an off-incidence angle artifact. This is especially helpful if the images are reassessed at a later time.

We have developed an alphanumeric system for ranking exercise levels (Box 16-2). The current exercise level may have an important impact on diagnosis, treatment, future exercise control, and prognosis. For instance, if a horse at pasture injured a SDFT, advising pasture rest would be contraindicated. A chart for ranking exercise levels can be duplicated easily, laminated, and taped to equipment for easy reference.

Clinical findings may be recorded concisely as follows:

Leg	Which Limb
S	Subcutaneous swelling on a scale of 0 to 5. This does not refer to tendinous or ligamentous enlargement.
L	Lameness on a scale of 0 to 5.
T	Thickening of a tendon or ligament on a scale of 0 to 5. This is independent of subcutaneous swelling.
Sen	Response to digital palpation of a tendon or ligament on a scale of 0 to 5.

H	Heat or skin temperature on a scale of 0 to 5.
TS	Distention of the digital flexor tendon sheath (DFTS) (tenosynovitis) on a scale of 0 to 5.
AS	Fetlock sinking (hyperextension of the metacarpophalangeal joint), either at rest or during movement, on a scale of 0 to 5.
Qualitative diagnosis	Comments on preliminary qualitative ultrasonographic interpretation.
New	Whether this is the first time this horse has been examined ultrasonographically for this complaint.
Re-Ck	A recheck of a previous injury.
Normal leg	This indicates which is the clinically normal limb, which may not be normal ultrasonographically. It is strongly recommended that both limbs be examined routinely.
Both abn	Both limbs are clinically abnormal.

Image Labeling

All ultrasonographic images should be labeled with the date of examination, the horse's name, the owner's or trainer's name, the limb being examined, and the location of the image. In addition, it is helpful to include the age, breed, and use of the horse and the current exercise level. Most machines automatically record the frequency of the transducer and the focal zone. If digital recording is used, a system of image backup is essential.

EXERCISE LEVELS

One of the basic concepts in the management of horses with tendon and ligament injuries is to relate increasing levels of exercise to increases in tendon and ligament loading. For instance, walking a Thoroughbred (TB) racehorse in hand results in far less SDFT loading (stretching) than racing at 35 mph. Understanding the current exercise level is important in interpretation of ultrasonographic information and advising management programs for controlled exercise during rehabilitation from an injury (see Box 16-2).

For example, if a TB racehorse with a SDFT injury of 4 months' duration were reexamined and the SDFT showed little improvement, despite box or stall rest, the veterinarian would conclude that the repair was of poor quality with a poor prognosis for a return to racing. However, if the horse had been turned out for 6 hours a day with other horses that ran around, the delayed healing would be interpreted as being caused by too much tendon loading and the lack of improvement would be attributed to low-level ongoing injury. The client would be advised to reduce the exercise level and would be given a somewhat more positive outlook for future racing soundness.

In the rehabilitation of a tendon or ligament injury, the odd exercise level numbers result in the most salient changes in tendon or ligament loading. Exercise level 1 is limited to walking, resulting in little structure loading, whereas exercise level 3 is a major step up in exercise and structure loading because it allows free movement of the horse. Exercise level 5 signals the return to active training. Finally, exercise level 7 is the ultimate goal of rehabilitation and is the return to maximal athletic use. During rehabilitation the ultrasonographer assesses the current

BOX 16-2

Exercise Level Grading Scale

Exercise Level	Type of Exercise Allowed
0	Complete stall rest.
1A	Handwalk for 15 to 30 minutes once a day.
1B	Handwalk ≥ 30 minutes a day or walk on a mechanical walker. We believe horses usually are more active walking on a mechanical walker than in hand.
2A	Thoroughbred (TB) and Standardbred (STB) racehorse, event horse (EV), and sports horse (SH): exercise level 1A/B plus trotting in hand for 5 to 10 minutes a day.
2B	TB racehorse, SH, and EV: trot under saddle 10 to 15 minutes once a day or swim. STB racehorses: walk only in the bike or swim. This level also includes 10 to 15 minutes of trotting on a treadmill.
3A	Small paddock turnout for all horses. Small paddock implies small enough not to be able to work up to a sustained canter or gallop.
3B	Large paddock turnout for all horses.
4A	TB and SH: 15 to 20 minutes a day of walk, trot, and canter under saddle, 3 days per week, plus any of the above levels. This level does not apply to most STBs.
4B	TB: 20 to 30 minutes a day of walk, trot, and canter under saddle, 3 to 4 days a week. TB racehorse: "ponying" (being led from another horse) on the racetrack. This level does not apply to most STBs.
5	TB racehorse and EV: all of the above plus normal galloping. STB racehorse: all of the above plus jogging. SH: all of the above plus normal arena flat work with limited low fence jumping where applicable. Dressage horses: normal work minus lateral movements and special gaits.
6	TB racehorse: all of the above plus faster gallops. EV: all of the above plus jumping. STB racehorse: all of the above plus training miles ≥ 2 : 10. SH: all of the above plus unlimited low fence jumping where applicable. Dressage: all of the above plus lateral movements and special gaits.
7	Contest horses (reiners, cutters, and so on): all of the above plus practicing specific turns and movements. In essence, this is the maximal work level for any type of athletic horse. TB and EV: racing, fast works, and competing. STB racehorse: training miles < 2 : 10 and racing. SH: showing, jumping, hunting, and so on. Dressage and contest horses: competing.

morphological status of a structure and advises changes in exercise levels consistent with those findings. Readily available and definable exercise levels make exercise decisions more efficient and consistent.

SCANNING TECHNIQUE

The basic objective of an ultrasonographic evaluation is to characterize the morphological characteristics of the soft

tissue structures and bony surfaces of each designated anatomical area. Although physical examination findings may direct the clinician's attention to a specific structure, a thorough examination of all soft tissue and bone surface structures is imperative. In many instances, lesions in more than one anatomical region may be identified and often result in a completely different recuperation regimen. To avoid off-incidence artifacts, the ultrasound beam must be perpendicular to the target structure. Although more than one structure may be perpendicular to the ultrasound beam simultaneously in either transverse or longitudinal images, often it is necessary to redirect the ultrasound beam to adequately examine all structures at each level. Initially the limb should be systematically examined from proximal to distal to assess the morphological features of the vasculature, periligamentous and peritendinous tissue, tendons, and ligaments. Once specific abnormal or normal structures are identified, each tendon or ligament is analyzed systematically by ultrasonographically targeting the transducer to the structure at each zone and simultaneously documenting the scan on tape, on print record, or by electronic storage.

ARTIFACTS

Artifacts can cause major problems with any imaging modality but are especially prevalent with ultrasonography because the operator steers the ultrasound beam and sets the instrument parameters. Three primary artifact sources are common with diagnostic ultrasonography: operator error, ultrasound-tissue interaction, and inherent instrument design artifacts. Nothing can be done about the limitations of the imaging system except to recognize the artifacts in special scanning situations. Sound-tissue interaction creates myriad artifacts, some of which are useful and help with diagnosis. Others are annoying and can be difficult to overcome. Readers are referred to several publications that address the majority of artifacts peculiar to ultrasonography.⁹⁻¹⁴ Operator error and ultrasound-tissue interactions are discussed further.

Operator Errors

Inadequate Skin Preparation

Excessively long or dirty hair and unclean skin attenuate the ultrasound beam and produce image artifacts. Improper scanhead coupling to the skin caused by a lack of gel or the presence of scabs or scurf is common (Figure 16-1). Artifacts created by improper skin preparation result from poor contact. Images may be dark even though gain settings may be set at the highest limits. The tendons do not have a fine texture and are more grainy or mottled than normal. Tendon margins may not be seen, and reverberation artifacts caused by trapped air within the hair may appear within images, especially if standoff pads are used. Hypoechoic streaks may be present in the images.

Ultrasound Beam Angle

Reflection of the ultrasound beam is dependent on the sound-interface and tissue-interface geometry. Ideally the ultrasound beam should strike tissue interfaces at 90 degrees to produce the best echo reflection back to the transducer crystals, which also act as receivers. If the beam

Fig. 16-1 • Transverse ultrasonographic images of the palmar metacarpal region. Improper skin preparation causes artifacts within the image on the right.

Fig. 16-2 • Transverse ultrasonographic images of the distal palmar aspects of the metacarpal region. The left deep digital flexor tendon image has a normal tendon fiber pattern. The right image has an apparent central core artifact (arrows) that was produced by slightly changing the angle of the ultrasound beam.

strikes a tissue interface at a smaller angle, a portion of the ultrasound is reflected away from the primary beam direction, and the interface is not seen as well or at all. This is especially important in the evaluation of tendons and ligaments in the metacarpal and metatarsal regions because the fibers usually are parallel to the skin. If the ultrasound sound beam is not perpendicular to a tendon in a transverse image, information is lost, and hypoechoic areas, which mimic lesions, are created (Figure 16-2). The problem is not seen in longitudinal images of the metacarpal or metatarsal region obtained using a linear array transducer because its surface is parallel to the fibers. However, with convex array and sector transducers that have divergent ultrasound beams, there are only small areas within longitudinal tendon fiber images in which valid information is found (Figure 16-3). In the divergent area of the beam, sound is reflected away from the beam path and is lost to the image. It is important not to confuse these areas with pathological conditions of the tendon or ligament. The ultrasound beam must be positioned parallel to the tendon fibers. Normal tendon or ligament fibers should be seen as

Fig. 16-3 • Longitudinal ultrasonographic image of the proximal metacarpal region. The arrows point to tendon and ligament sections where the ultrasound beam is at 90 degrees, which allows the fibers to be seen. The remaining parts of the image provide no diagnostic information.

Fig. 16-4 • Longitudinal ultrasonographic images of the palmar metacarpal region. The left image was obtained with a linear array transducer parallel to the tendon fibers. The right image was obtained with the transducer slightly oblique to the tendon fibers, causing them to appear as short segments instead of continuous fiber strands (arrows).

continuous linear echogenic structures across the image (Figure 16-4). If the transducer is turned slightly, the fibers appear as short linear segments as the beam cuts obliquely across the longitudinal axis. Because fiber alignment is an important criterion to assess in diagnosis and rehabilitation of tendon and ligament injuries, care must be taken to not create this artifact.

Improper Gain Settings

Ultrasound machines have gain settings referred to as *overall*, *near*, and *far* gain. As ultrasound penetrates normal soft tissues, it is attenuated at the rate of 1 dB/cm of tissue thickness per megahertz. Obesity and dehydration cause greater attenuation and can limit penetration. Because energy is lost from the ultrasound beam as it passes into the tissues, the instrument gain must be increased to allow echo detection from the deeper tissue depths. Overall gain changes the brightness and darkness over the entire image. The near-gain adjustment affects the echoes closest to the

Fig. 16-5 • **A**, Transverse sector scan ultrasonographic image of the palmar metacarpal region with the near gain set too high. The superficial digital flexor tendon (SDFT) echoes are too bright and cannot be differentiated. Acoustic shadowing (large arrow) is caused by flexor tendon and reverberation artifacts caused by the standoff pad (small arrows). **B**, The near gain was set too low, so the SDFT cannot be seen (arrows).

transducer. Increasing the near gain brightens the echoes, and decreasing it darkens them. The far gain affects the deeper aspect of the image. Some machines display a time-gain compensation curve at the side of the screen. Adjustment of the gain settings should produce an image in which the gray scale is similar over the entire image. Bright whites in the near field should prompt decreasing the near gain; conversely, if echoes are difficult to see, increase in the gain is necessary (Figure 16-5). Improper near-gain settings are the most common error in settings. Visibility of far-field echoes is enhanced by far-gain increases.

Improper Focal Zone Use

Before the advent of moveable and multiple focal zones, transducers had fixed focal points and well-defined focal zones. The ultrasound beam was narrowest in the focal zone in which the lateral resolution produced the best image quality. If the tissues of interest were outside the focal zone, image quality was not ideal. Use of transducers with appropriate focal zones became necessary. If a sector transducer is used to image the SDFT, a standoff pad is necessary to place the tendon in the focal zone. Variable focal zones have eliminated this problem and allow focal

Fig. 16-6 • Transverse ultrasonographic images of the proximal metacarpal region. A focal lesion in the suspensory ligament (arrows) is visible on the left image. The lesion disappears (circle) in the right image because the focal zones are improperly placed. Arrows in the left and right margins point out the focal zone levels.

zone placement throughout the image depth. Modern linear array and convex array transducers have multiple and moveable focal zones. However, they need to be set in the proper locations to investigate the areas of suspected abnormality. If the focal zones are not placed properly, clinically significant tendon and ligament fiber damage can be overlooked (Figure 16-6).

Incorrect Frequency Transducer

Tissue depth dictates the optimal transducer frequency. Tissues within 5 to 7 cm of the skin surface should be examined with a 7.5-MHz or higher-frequency transducer. A 5.0-MHz transducer is required to examine tissues from 7 to 12 and up to 15 cm (depending on the instrument), and a 3.0-MHz or lower-frequency transducer is necessary for tissues 15 to 30 cm deep.

Imaging the digital flexor tendons or SL with a transducer of 5.0 MHz or less results in major compromise of image quality because of lateral beam width artifact. Two types of resolution are peculiar to ultrasound. Resolution along the beam axis, or axial resolution, is frequency dependent; the higher the frequency, the better the axial resolution. Resolution in the transverse plane, or lateral resolution, is dependent on the width of the ultrasound beam; the better the focusing or sound beam narrowing, the better the lateral resolution. Smaller crystals produce narrower sound beams, hence increased lateral resolution. A transducer with a minimum frequency of 7.5 MHz should be used for superficial tendons and ligaments for best axial and lateral resolution.

Recording Images

Thermal printers were the most popular method for recording ultrasonographic images, and some are still in use. Brightness may be set too high, causing echoes to have no differentiating characteristics (Figure 16-7), or set too low, causing the image to be too dark (Figure 16-8). The same problem occurs with contrast settings; too high a setting causes excessive contrast, and too low a setting causes the image to be washed out and too dark.

It is important to consult the instruction manual to ensure that the image parameters are set properly. Proper

Fig. 16-7 • Transverse ultrasonographic images of the metacarpal region obtained without a standoff pad showing the deep digital flexor tendon (DDFT), accessory ligament of the DDFT (ALDDFT), and the suspensory ligament (SL). The brightness is set too high, causing tendon fiber detail loss.

Fig. 16-8 • Transverse ultrasonographic images of the metacarpal region obtained without a standoff pad showing the deep digital flexor tendon (DDFT), accessory ligament of the DDFT (ALDDFT), and the suspensory ligament (SL). The brightness is set too low, causing the image to be too dark.

settings also are necessary for the paper type. Interpreting improperly recorded (suboptimal) images causes substantial diagnostic error. Images must be assessed for photographic quality to preclude overlooking of lesions or overinterpretation. Suboptimal images should be repeated to preclude inaccurate interpretation and misdiagnosis. Images should always be frozen before capture.

Recording digital images on floppy disks was an effective way to capture all of the information. Depending on the system, images were recorded in bitmap (BMP) or Joint Photographic Experts Group (JPEG) formats. These were archived on hard drives and could be sent by e-mail if desired. External image capture devices functioned well, and some instruments with internal floppy drives are still in use. Digital archiving is now becoming routine. Various video formats, including video home system (VHS), 8-mm, S-Video, cineloop, and videodisk formats, are used to

record motion. Recording static tissue (e.g., tendon) studies while moving the scanhead during recording can produce errors if the transducer is moved too rapidly for the frame rate to keep pace. Tendon examinations should be performed at relatively slow frame rates, as low as 7 per second, if multiple focal zones are activated. Moving the scanhead too fast causes ghosting of the image that blurs the anatomy. Activating multiple focal zones and the resultant slow frame rate can cause a similar problem with minimal scanhead movement.

Standoff Pads

Standoff pads are necessary when scanning structures near the skin, such as the SDFT and SL branches. Artifacts are produced each time they are used and can compromise image quality. It is important to recognize them. Transducers with built-in fluid standoff devices are no different. The artifacts are caused by reverberation within the standoff material and occur at a depth equaling the pad thickness (see Figure 16-5), which may obscure detail. For instance, examination of SL branches with a standoff pad can place artifacts in or near the axial border of the SL. This technique can obscure small axial border tears that are fairly common in horses. If the standoff pad thickness produces interfering artifacts, the SL branch should be examined with and without a standoff pad.

Ultrasound Tissue Interaction Artifacts (Horse-Produced Artifacts)

Ultrasonographic images are composed of returning echoes from many tissue interfaces, regardless of whether they are real or artifact. Some artifacts are useful in diagnosis and provide clues to tissue composition. Others are annoying and do not contribute to the diagnosis. Echoes are generated at tissue interfaces because of differences in acoustic impedance. Acoustic impedance is the product of tissue density (grams per cubic centimeter) and sound propagation velocity (meters per second). Substantial changes in either parameter produce acoustic barriers proportional to the magnitude difference, which causes sound reflection at the interface. Higher (brighter) amplitude echoes are created by greater acoustic impedance differences at tissue interfaces.

Skin Surface Contact

Debris and air trapped in the hair create large acoustic impedance differences and do not allow adequate sound penetration (see Figure 16-1).

Acoustic Enhancement

Whenever ultrasound passes through nonattenuating tissues, such as fluid with few or no interfaces, a slight increase in ultrasound intensity occurs in addition to less attenuation. The adjacent tissues attenuate the ultrasound normally. This causes brighter (enhanced) echoes deep to the less attenuating tissues. A good example is the enhancement seen deep to the metacarpal and metatarsal blood vessels. The SL has brighter echoes deep to the blood vessels, whereas between the blood vessels it is less echogenic (darker); it is tempting to interpret such results as abnormal (Figure 16-9). This is an inherent, tissue-produced artifact that can lead to interpretation errors but may help identify less attenuating areas within tissues such as muscle.

Fig. 16-9 • Longitudinal ultrasonographic image (*left*) and transverse ultrasonographic image (*right*) of the metacarpal region obtained without a standoff pad showing the deep digital flexor tendon (DDFT), accessory ligament of the DDFT (ALDDFT), and the suspensory ligament (SL). The tissue brightness (*short arrows*) increases deep to the blood vessels. An anechoic line (*arrows*) extends deep to the blood vessels (*arrowheads*).

Fig. 16-10 • Longitudinal ultrasonographic images of the proximal palmar metacarpal region. Proximal is to the left. Refractive scattering (*arrows*) caused by the veins between the origin of the suspensory ligament (SL) and the accessory ligament of the deep digital flexor tendon (ALDDFT). DDFT, Deep digital flexor tendon.

Refractive Scattering

If the ultrasound beam is not perpendicular to a tissue interface, hypoechogenic artifacts are caused by refraction. These artifacts can be a major problem in assessing the origin of the SL because of the anastomotic veins between it and the ALDDFT (Figure 16-10). The curved blood vessel walls create hypoechogenic lines that extend deep to the vessel walls in transverse images (see Figure 16-9). This is called *refractive scattering* and should not be misinterpreted as a lesion.

Acoustic Shadowing

A high acoustic impedance difference blocks the ultrasound beam and causes an anechogenic shadow deep to the reflecting interface. Bone and other mineralized tissue

are much denser than soft tissues, and the sound propagation velocity is much faster. This creates an impenetrable acoustic barrier, and characteristically the reflector surface has bright echoes and the deeper tissues cannot be seen. These artifacts are useful because they identify soft tissue mineralization (see Figure 16-5). Bone surfaces are easily recognized because of shadowing. Dense scar tissue may create incomplete shadowing.

Reverberation

Reflection of ultrasound back and forth to the transducer from high acoustic impedance interfaces produces reverberation artifacts. The classic example is an air-filled lung surface that produces characteristic concentric reverberation echoes. Reverberation artifacts are not a major problem in tendon and ligament scanning; however, they can be important in certain circumstances. Gas production by anaerobic bacteria and air accidentally injected during diagnostic analgesia are two examples in which reverberation can be found in soft tissues. Standoff pads also create reverberation artifacts (see Figure 16-5).

Mirror Image Artifacts

Mirror image artifacts are not common problems in musculoskeletal ultrasonography and are more common in thoracic and abdominal scanning. They usually are found deep to interfaces that are highly reflective, such as air-filled lung.

Future Technology

Speckle reduction software, cross-beam scanning techniques, and the use of tissue harmonics are changing the appearance of ultrasound images. The images are smoother and lack the historically present “grainy” appearance that is common to ultrasound images. These innovations are gradually being accepted in medical imaging but are still relatively new. Some machines allow viewing the cross-beam imaging in a split-screen format with the original “grainy” images. This allows users to compare the two and to become familiar with the newer innovations. Off-axis or off-incidence scanning techniques that help to differentiate fluid from scar tissue within connective tissue structures have recently been introduced into veterinary imaging as well. With these newer technologies, artifacts peculiar to them will be defined as they find their place in medical and veterinary imaging.

TERMINOLOGY AND QUANTITATIVE MEASUREMENTS

The basis of diagnosis is to determine the morphological variation from normal, which is not always easy. The goal is to determine the size, shape, echogenicity, fiber pattern, and surrounding inflammatory reaction of any structure. These findings should be considered carefully in conjunction with clinical impressions and the current athletic use of the horse. Box 16-3 lists parameters used for characterizing tendon and ligament lesions.¹⁵

Echogenicity

Echogenicity refers to the whiteness or brightness of a structure. Each tendon and ligament has a characteristic

BOX 16-3

Parameters Used for Characterizing Tendon and Ligament Lesions

- Region or location of the lesion
- Length of the lesion
- Alteration in echogenicity
- Pattern of altered echogenicity (i.e., homogeneous, heterogeneous, focal, and diffuse)
- Alteration of fiber pattern in longitudinal images
- Percent of cross-sectional area of tendon injury
- Changes in the character of the lesion over time

BOX 16-4

Type Scores

Score	Description
0	Isoechogenic
1	Slightly hypoechogenic; mostly echogenic
2	Mixed echogenicity (50% echogenic and 50% anechogenic)
3	Mostly anechogenic or anechogenic

echogenic pattern at specific anatomical sites. Lesions vary in echogenicity depending on morphological consistency at the time of the examination. A scoring system can be used to improve objectivity when assessing the severity of an injury or the response to therapy (Box 16-4). Such a system may improve case management and illustrate to the client the changes in echogenicity that correlate with repair of an injury.

The following terms are used to describe ultrasound images (bear in mind that a tissue creates/generates echos and is echogenic; a normal tendon is isoechogenic; a lesion on an ultrasonographic image may appear anechoic because the damaged tendon tissue is anechogenic):

Isoechoic	The echogenicity of the structure is normal and is scored as 0.
Hypoechoic	The lesion is less than isoechoic. There are two categories of reduced echogenicity defined under the term <i>hypoechoic</i> . The first is gray or slightly off-white. This is a type 1 lesion (Figure 16-11). If the lesion is of mixed black and white tones, it is scored as a type 2 hypoechoic lesion (Figure 16-12).
Anechoic	The lesion is mostly black, a type 3 lesion.
Hyperechoic	Denoix ⁸ grades hyperechoic lesions as hyperechoic 1, which indicates that the lesion is brighter than isoechoic and represents dense scar tissue without an acoustic shadow. Hyperechoic 2 lesions (see Figure 16-5) represent soft tissue mineral deposition, which is characterized by casting an acoustic shadow. These echo patterns are uncommon and are generally seen in long-standing and repetitively injured tendons and ligaments.

Fig. 16-11 • Transverse (left) and longitudinal (right) ultrasonographic images of zone 3A of the metacarpal region obtained using a standoff pad. A type 1 hypoechoic lesion is present in the superficial digital flexor tendon (SDFT) (arrow). (See text for zone descriptions.) DDFT, Deep digital flexor tendon; SL, suspensory ligament.

Fig. 16-12 • Transverse (left) and longitudinal (right) ultrasonographic images of zone 3A of the metacarpal region. A type 2 hypoechoic lesion is present in the superficial digital flexor tendon (SDFT; arrows). DDFT, Deep digital flexor tendon; ICL, inferior check ligament (accessory ligament of the deep digital flexor tendon); SL, suspensory ligament.

Fiber Alignment Pattern Assessment

Assessment of fiber bundle alignment in longitudinal images determines the nature of a tendon's or ligament's fiber arrangement. Normally the fibers are aligned in parallel except in some anatomical areas, such as the origin of the hindlimb SL. When injury occurs, the expected parallel fiber pattern is disrupted. During healing of an injury, random orientation and cross-linking of new collagen fibers may create scar tissue that results in a substantial improvement in echogenicity but constitutes a poor scaffold for parallel alignment of fibers. Parallel alignment is more physiologically advantageous than random orientation of a scar, because randomly oriented scar tissue is susceptible to reinjury, especially during increased exercise. In a new injury or reinjury, longitudinal images are used

BOX 16-5

Fiber Alignment Scoring

Score	Definition
0	Target path $\geq 75\%$ parallel
1	Target path 50% to 75% parallel
2	Target path 25% to 50% parallel
3	Target path $\leq 25\%$ parallel

to confirm the presence of a lesion identified in transverse images. When monitoring repair, fiber alignment can be assessed.

The longitudinal image must be obtained through the area of fiber bundle compromise to accurately assess the lesion. This is easy if a large proportion of the cross-sectional area (CSA) is involved. If a lesion is small or located on the margins of a tendon or ligament, it is more difficult. It is important to remember that fiber alignment, *not* echogenicity, is being assessed. In some instances, such as new injuries or reinjuries in the SDFT, the echogenic and fiber alignment scores (FASs) may be the same. This is rarely true for SL injuries.

An arbitrary scoring system for fiber alignment has been reported (Box 16-5).^{6,8} In this system, a score is assigned to semiquantitate fiber alignment of the target path. The veterinarian should bear in mind that the target path is wide with large lesions, but in small lesions it is quite narrow.

During repair the echogenicity score usually improves at a more rapid rate than the scar remodeling and FAS. The difference in these scores may be important for tailoring an appropriate controlled exercise program. A delay in fiber alignment improvement suggests that scar remodeling must continue and prompts conservative progression in exercise management.

It is more difficult to identify the target path of fiber bundles during healing once echogenicity has improved. Printed or electronically stored images of the initial examination can be reviewed to identify the exact location of the lesion. If the original scans are not available, one author (RLG) prefers to scan each zone from medial to lateral (or vice versa) and document the longitudinal image with the most abnormal fiber alignment. FAS (see Box 16-5) has been useful in predicting the prognosis for return to racing.¹⁶ A horse with mean FAS of less than or equal to 0.5 at 4 months after treatment of SDFT was more likely to return to racing than a horse with a mean FAS greater than 0.5. An improvement in total FAS of greater than 75% was associated with a greater chance of returning to racing.¹⁷

Cross-Sectional Area

CSA measurements of transverse images of a ligament or tendon are useful, especially in assessing a subtle injury or determining the clinical significance of a localized, focal hypoechoic fiber bundle path. When assessing the proximal aspect of the SL, it is useful to determine whether a focal hypoechoic fiber bundle is likely to be a lesion or the remains of muscle fibers. An injured tendon or ligament usually is enlarged, and although this finding may not be obvious subjectively, measurements of CSA confirm structural thickening.

Fig. 16-13 • Transverse (left) and longitudinal (right) ultrasonographic images of zone 3A of the metacarpal region. The cross-sectional area (CSA) of the superficial digital flexor tendon (SDFT) is 3.05 cm². A dorsolateral type 1 hypoechoic lesion is present; the lesion is 43 mm² and represents 14.1% of the CSA of the tendon. The fiber alignment score of the targeted fiber path is 3 (between arrows). DDFT, Deep digital flexor tendon; SL, suspensory ligament.

CSA is also a useful parameter to evaluate the quality of repair, because decreasing size during rehabilitation indicates resolution of the inflammatory component of healing or may indicate favorable scar remodeling. Randomly oriented scars usually form in a rounded fashion and occupy more space. As the scar remodels into a more parallel alignment, less space is necessary, resulting in a reduction in CSA.

The transducer must be perpendicular to the structure to obtain accurate CSA data; otherwise the CSA may be falsely enlarged. The most common technique is to trace the structure on the monitor and the computer software automatically calculates the size. This technique also can be used to calculate lesion size and the proportion of the CSA involved (Figure 16-13). Initially this method of quantifying CSA may be time-consuming, especially when several structures are being assessed. Eventually the veterinarian can become extremely proficient at producing accurate measurements.

One author (RLG) uses a computer-assisted method that is not commercially available. Transverse images are traced with a microfine-point felt pen after the ultrasonographic study. With a digitizing pad and software program, surface area data are produced from the tracings of structures and lesions. This method is equally accurate but saves time because scans can be traced more quickly and at a more convenient time. The disadvantage is that the final quantitative information is not immediately available, but it does allow the clinician time to review the images before giving a conclusion to the owner. An alternative method is to save images on a computer disk using commercially available software (Metron-V, EponaTech, Creston, California).

Another simple and inexpensive method to determine structure and lesion CSA is creation of thermal images at all zones, and then at a convenient time, use of handheld calipers to make structures and lesions into two-dimensional squares or rectangles. This is done by

Fig. 16-14 • Transverse (left) and longitudinal (right) ultrasonographic images of zone 2B, obtained using a standoff pad. There is a large lateral border type 3 lesion of the superficial digital flexor tendon (SDFT; horizontal arrow) confirmed on longitudinal scan (horizontal arrow). DDFT, Deep digital flexor tendon; MIZ-ES, maximal injury zone echo score; MIZ-FAS, maximal injury zone fiber alignment score; SL suspensory ligament.

measuring the palmar- or plantar-to-dorsal length and the medial-to-lateral length. These measurements are multiplied to determine the CSA. CSA obtained with handheld calipers is likely larger than the actual size. However, absolute values are less important than the relative difference between normal and suspected abnormal values. Thus if measurements are performed in a consistent manner, handheld calipers provide valid relative CSA data.

Relative sizes are best obtained by comparing the injured limb with the normal contralateral limb, but this is not possible if the injury is bilateral. The veterinarian must rely on the expected values for the age, size, and breed of the horse and level or zone of the image based on personal experience and previous images if available. Normal values for various structures are difficult to determine, and few studies have been published. Normal values for tendon and ligament sizes for TB and STB horses have been reported.¹⁸ It is essential to measure both limbs at the same depth setting on the ultrasound machine.

In summary, quantifying the ultrasonographic image using echogenicity and FASs, along with CSA of the lesion, provides a powerful resource to aid in interpreting lesions (Figure 16-14). When an injury is assessed from proximal to distal, these scores can be summed to estimate the volume of the injury. These values can be used to categorize the injury and to monitor repair objectively.

ZONE DESIGNATIONS

The anatomical location of an ultrasonographic image can be designated by measuring the distance from a fixed landmark, such as the accessory carpal bone, or dividing the limb into zones.

Distal Aspect of Forelimbs

The palmar metacarpal and metacarpophalangeal regions may be separated into seven zones, or eight zones if the

Fig. 16-15 • Ultrasonographic zone designations for the carpal (C) and metacarpal (MC) regions.

medial aspect of the carpus is included (Figure 16-15). The pastern also may be divided into zones (see page 198). Many of these zones have unique anatomical features. The measurements outlined in the following text refer to a 16.1-hand TB horse.

Zone Definitions

Zone 0

Zone 0 (approximately 5 cm in length) is located along the medial aspect of the carpus adjacent to the accessory carpal bone (Figure 16-16). Off-incidence angle artifacts may be present on the dorsal border of the DDFT, and rarely, hypoechogenic muscle bundles are seen (Figure 16-17). At this level the SDFT is uniform in echogenicity, but further proximally are hypoechogenic muscle bundles that should not be mistaken for lesions. The carpal sheath, common digital artery, and palmar carpal fascia are visible.

Zone 1A

Zone 1A extends from approximately 0.5 to 4 cm distal to the base of the accessory carpal bone. The SDFT is slightly medially placed, oval, and readily visible on the midline. The carpal retinaculum covers its palmar border proximally. The common digital artery lies close to the medial border of the SDFT. The DDFT is triangular, and the lateral border is more rounded (Figure 16-18). The ALDDFT and SL are rectangular. The medial and lateral borders of the ALDDFT and SL may not be visible from the palmar midline; therefore the transducer should be moved medially and laterally. However, to measure CSA of these

Fig. 16-16 • Transverse ultrasonographic images of a forelimb zone 0 obtained along the medial aspect of the accessory carpal bone with a standoff pad. The left image is focused on the superficial digital flexor tendon (SDFT), and the right image is focused on the deep digital flexor tendon (DDFT). CC, Carpal canal; Flex Carp Rad, flexor carpi radialis; Lat, lateral; L Pal V, lateral palmar vein; M Pal A, medial palmar artery; M Pal N, medial palmar nerve; M Pal V, medial palmar vein; Med, medial.

Fig. 16-17 • Transverse (left) and longitudinal (right) ultrasonographic images of the forelimb zone 0 obtained from the medial aspect of the carpus, immediately proximal to the accessory carpal bone, without a standoff pad. Note the centrally located muscle bundles of the superficial digital flexor tendon (SDFT) and the deep digital flexor tendon (DDFT). This is normal and should not be confused with a lesion. CC, Carpal canal; M Pal A, medial palmar artery.

structures, the veterinarian should use what can be seen from the palmar aspect. In most horses, anechogenic fluid in the carpal sheath is seen between the dorsal border of the DDFT and the palmar border of its accessory ligament. The medial aspect of the rectangular carpal sheath is wider than the lateral border.

The origin or entheses of the SL is approximately 3 to 4 cm long. The SL rapidly increases in thickness from palmar to dorsal as it descends distally. In contrast, the

Fig. 16-18 • Transverse ultrasonographic images of the forelimb zone 1A. Carpal retinaculum (arrow). Fig. 16-19 • Transverse (left) and longitudinal (right) (proximal is to the left) ultrasonographic images from zone 1A of a forelimb obtained without a standoff pad. There is a ligamentous band (ligamentous segment of origin of suspensory ligament that originates from the palmar carpal fascia [FB; small arrows]) extending from the palmar aspect of the suspensory ligament, passing palmarly over the anechogenic joint recess of the carpometacarpal joint (large horizontal arrow) and inserting proximally on the dorsal surface of the accessory ligament of the superficial digital flexor tendon. CS, Carpal sheath; DDFT, deep digital flexor tendon; ICL, accessory ligament of the DDFT; SDFT, superficial digital flexor tendon.

ALDDFT rapidly decreases in thickness from palmar to dorsal. Comparative CSA measurements in each forelimb should be done at precisely the same distance distal to the accessory carpal bone in zone 1A.

In the proximal metacarpal region a ligamentous band often extends proximally from the origin of the SL to insert on the palmar carpal fascia of the distal row of carpal bones (Figure 16-19). It is located between the dorsal border of the ALDDFT and the palmar recess of the carpometacarpal joint, which lies between the fibrous band and the third metacarpal bone (McIII). Anechogenic fluid in the

Fig. 16-20 • Transverse (left) and longitudinal (right) (proximal is to the left) ultrasonographic images from zone 1A, 2.5 cm distal to the base of the accessory carpal bone, without a standoff pad. There is a firm attachment of the suspensory ligament (SL) to the third metacarpal bone (MC₃) on the transverse (single vertical arrow) and the longitudinal (double vertical arrows) views. CS, Carpal sheath; DDFT, deep digital flexor tendon; ICL, accessory ligament of the DDFT; SDFT, superficial digital flexor tendon.

Fig. 16-21 • Transverse ultrasonographic images at the distal extent of zone 1A (3.0 cm distal to the base of the accessory carpal bone), without a standoff pad. The palmar-to-dorsal dimension of the suspensory ligament (SL) is the greatest for this zone in a normal horse. CS, Carpal sheath; DDFT, deep digital flexor tendon; ICL, accessory ligament of the DDFT, MC₃, third metacarpal bone; SDFT, superficial digital flexor tendon.

carpometacarpal joint should not be confused with a lesion of the SL. The proximal aspect of zone 1A is proximal to the entheses of the SL on the McIII.

At 2.5 cm distal to the accessory carpal bone the origin of the SL is firmly attached to the McIII (Figure 16-20). Entheseal fiber tearing usually occurs 1 to 3 cm distal to the accessory carpal bone. The oblique orientation of the McIII at the origin of the SL attachment can be seen on a longitudinal view (see Figure 16-20). Figure 16-21 is at the

distal extent of zone 1A and the distal extent of the enthesis of the SL. Note the palmar to the dorsal width at this point in zone 1A and the firm bony attachment of the entire dorsal surface of the SL. In this example, there is complete dorsal attachment of the SL. However, in many normal horses the origin of the SL has a bilobed appearance (medial and lateral attachments), with a rounded or triangular hypoechogenic area dorsally in the midline. Clinicians must be cautious not to interpret this as a focal tear. Rarely the origin of the SL can be injured in this central location, but generally the size and shape of the hypoechogenic region are changed.

Zone 1B

Zone 1B extends from approximately 4 to 7 cm distal to the accessory carpal bone. At this level the slightly crescent-shaped SDFT is on the midline over the oval DDFT. There are no unique anatomical features of this zone that identify it, and its location is determined by measurement. In all midmetacarpal zones, as in zone 1A, the medial and lateral borders of the SL and ALDDFT may not be visible from the palmar midline. The transducer must be moved medially or laterally to identify a focal peripheral lesion of one of these structures. At times, the dorsal border of the SL can be difficult to identify because of the density of the periligamentous, fibrous connective tissue. To assist in defining that border, it can be helpful to split the screen and place the longitudinal image adjacent to the transverse image. This technique clearly demarcates the dorsal and palmar borders (Figure 16-22).

Zone 2A

Zone 2A extends from approximately 7 to 10 cm distal to the accessory carpal bone. The same comments apply for this zone as for zone 1B.

Fig. 16-22 • Transverse (left) and longitudinal (right) (proximal is to the left) ultrasonographic images of zone 1B (5 cm distal to the base of the accessory carpal bone) obtained without a standoff pad. The down arrows mark the palmar border of the suspensory ligament (SL), and the up arrows mark the dorsal border. DDFT, Deep digital flexor tendon; ICL, accessory ligament of the DDFT, MC₃, third metacarpal bone; SDFT, superficial digital flexor tendon.

Zone 2B

Zone 2B extends from approximately 10 to 14 cm distal to the accessory carpal bone. One unique feature of this zone is an obliquely coursing nerve located subcutaneously on the palmar surface of the SDFT. This nerve (the communicating branch of the medial palmar nerve) and associated small vessels are a common site for a bandage pinch or “cording” swelling that suggests a primary tendon injury. Overall the anatomical relationships of tendons and ligaments are similar to zones 1B and 2A. The SDFT and ALDDFT are more crescent shaped and smaller from palmar to dorsal. At this level the carpal sheath still can be identified ultrasonographically.

Zone 3A

Zone 3A extends from approximately 14 to 18 cm distal to the accessory carpal bone. Several anatomical features characterize this zone. The first is that in many horses with tenosynovitis, this is the initial zone that incorporates the origin of the DFTs.

The SDFT is crescent shaped and smaller from palmar to dorsal but wider from medial to lateral. The ALDDFT inserts into the DDFT. In transverse images normal crescent-shaped hypoechogenic fiber bundles are seen between the dorsal surface of the DDFT and the palmar surface of its accessory ligament. The carpal sheath generally is not appreciated in this zone.

At the region of the ALDDFT insertion onto the DDFT, the two structures can clearly be separated ultrasonographically, although grossly they are conjoined. When measuring the CSA of the DDFT, the ALDDFT can be separated from the DDFT, which results in a reduced DDFT CSA, or included with it, which yields a more correct CSA determination of the DDFT. The method used is personal preference and results in valid information, provided it is consistent.

Zone 3A is just proximal to the bifurcation of the SL. In zone 3A the SL is still a single structure, but the medial and lateral borders become more rounded and the central region may be less echogenic. This is a common site of injury, especially in STB racehorses. At times it can be quite difficult to establish structural borders in acute injury. A longitudinal image viewed adjacent to a transverse may be helpful (Figure 16-23).

Zone 3B

Zone 3B is larger (approximately 5 cm in the average adult horse) than more proximal zones and is the region in which the SL bifurcates into medial and lateral branches. The zone extends from 18 to 23 cm distal to the accessory carpal bone. Anatomical structures include the DFTs; the manica flexoria, a fibrous band extending from the medial and lateral borders of the SDFT and encompassing the DDFT that is associated with a thecal space; and the intersesamoidean space and ligament with associated connective tissue and vasculature. The SDFT decreases in size from palmar to dorsal and widens from medial to lateral. The DDFT becomes ovoid. CSA measurements should be made at identical sites distal to the accessory carpal bone for accurate comparisons between limbs.

The SL branches must be examined individually from palmaromedial and palmarolateral aspects of the limb with a standoff pad. If the ligament is enlarged, no standoff pad is required. The length of a metacarpal SL branch is about

Fig. 16-23 • Transverse (left) and longitudinal (right) (proximal is to the left) ultrasonographic images from zone 3A (15 cm distal to the base of the accessory carpal bone), in which the suspensory ligament (SL) bifurcates. DDFT, Deep digital flexor tendon; ICL, accessory ligament of the DDFT; MC₃, third metacarpal bone; SDF, superficial digital flexor tendon.

Fig. 16-25 • Transverse (left) and longitudinal (right) ultrasonographic images of zone 3C obtained without a standoff pad. Vertical and horizontal arrows indicate a normal interosseous ligament. DDF, Deep digital flexor tendon; ISL, interosseous ligament; Lat Prox Ses, lateral proximal sesamoid bone osseous shadow; MC₃ Sag Ridge, sagittal ridge of third metacarpal bone; Med Prox Ses, medial proximal sesamoid bone shadow.

Fig. 16-24 • Transverse (left) and longitudinal (right) (proximal is to the left) ultrasonographic images of zone 3B-MD (medial placement of the transducer at the distal extent of the insertion of the medial branch of the suspensory ligament onto the medial proximal sesamoid bone). M PSB, Bone border of the abaxial medial proximal sesamoid bone; M SLB, medial suspensory ligament branch.

6 cm. To increase data points for CSA comparison, each branch is divided into three 2-cm subzones within zone 3B. For the medial branch, the zone designations are 3B-MP (medial proximal), 3B-MM (medial middle), and 3B-MD (medial distal) (Figure 16-24). For the lateral branch the zone designations are 3B-LP (lateral proximal), 3B-LM (lateral middle), and 3B-LD (lateral distal). The proximal and middle segments of each branch are oval, and the distal segment is more triangular.

Zone 3C

Zone 3C extends from 23 to 28 cm distal to the accessory carpal bone and basically includes tissues on the palmar

aspect of the metacarpophalangeal joint. The characteristic features of this zone are the presence of the bony shadows of apices of the proximal sesamoid bones (PSBs), the presence of the palmar annular ligament (PAL), and the interosseous ligament (Figure 16-25).

Distal Aspect of Hindlimbs

The anatomical location of an ultrasonographic image can be designated by measuring the distance from a fixed landmark, such as the tuber calcanei or tarsometatarsal joint, or reference to a numbered zone. Most distal limb anatomical features are the same as in the forelimb. However, because of the added length of the SDF or DDFT and the existence of the plantar ligament (long plantar tarsal ligament), the metatarsal zones move up one number.

In the hindlimb, zone 1 includes the plantar aspect of the tarsus (see Figure 78-3). In an adult horse, this is approximately 16 cm in length. Zone 1 is subdivided into two 8-cm zones, 1A and 1B. The most proximal zone of the metatarsal region is zone 2, which is subdivided into 2A and 2B; the middle third is zone 3, which is subdivided into zones 3A and 3B; and the distal aspect is zone 4, which is subdivided into zones 4A, 4B, and 4C (Figure 16-26).

Hindlimb Zones

Zone 1A

Zone 1A extends to 8 cm distal to the tuber calcanei (Figure 16-27; see Chapter 78). The SDF is slightly crescent shaped and located subcutaneously. Deep to the SDF is the origin of the plantar ligament. Occasionally the subcutaneous bursa or the subtendonous calcanean bursa or both bursae may be seen. The entire width of the SDF may not be observed on a single midline view, but useful CSA data can be obtained. The extreme medial and lateral borders of the SDF and the retinacular attachment to the calcaneus may be more visible with slight medial and lateral placement of

Fig. 16-26 • Ultrasonographic zone designations for tarsus and metatarsus.

Fig. 16-27 • Transverse (left) and longitudinal (right) (proximal is to the left) ultrasonographic images of the plantar tarsus (zone 1A, 5 cm distal to the tuber calcanei) obtained using a standoff pad. PL, Plantar ligament or long plantar tarsal ligament; SDFT, superficial digital flexor tendon; TC, plantar border of the calcaneus.

the transducer. The plantar ligament is located on the midline, firmly attached to the calcaneus, with its origin approximately 3 cm distal to the tuber calcanei. The DDFT and tarsal sheath must be viewed individually by medial positioning of the transducer. The origin of the plantar ligament widens in a plantar-to-dorsal plane rapidly in this

Fig. 16-28 • Transverse ultrasonographic images from zone 1B, 5 cm distal to the tuber calcanei, obtained using a standoff pad. Medial is to the right. The left image is slightly lateral of midline to highlight the plantar ligament (PL; between arrows), and the right image is slightly medial of midline to highlight the superficial digital flexor tendon (SDFT) and the deep digital flexor tendon (DDFT). C, Osseous border of the calcaneus; L, lateral; M, medial; PL, plantar ligament or long plantar tarsal ligament.

zone. Accurate comparative CSA data require precise anatomical positioning on both hindlimbs. Usually at this level, no visible muscle bundles of the DDFT are seen, but clinicians must be aware of this possibility and not interpret them as a core lesion. At 5 cm distal (zone 1B) to the tuber calcanei, the plantar ligament is roughly triangular and has multiple septated bundles that are all included in measurement of the CSA (Figure 16-28).

Zone 1B

Hindlimb zone 1B includes the distal half of the tarsus, extending from 8 to 16 cm distal to the tuber calcanei. Numerous images must be obtained from the plantar midline to assess the SDFT, from plantaromedial to assess the DDFT, and from slightly lateral to the midline to assess the plantar ligament. A wedge-shaped fibrous band emanates from the medial border of the SDFT and the fascia of the fibrous tarsal sheath and surrounds the DDFT (see Figure 16-28). There is a narrow anechoic space representing fluid in the tarsal sheath separating the DDFT and the plantar ligament. The plantar ligament decreases in plantar to dorsal size as it courses distally; it has a firm entheses to the plantar aspect of the fourth tarsal bone and inserts onto the head of the fourth metatarsal bone (MtIV).

Zone 2A

Zone 2A is the first metatarsal zone and includes the origin of the SL (approximately 16 to 21 cm distal to the tuber calcanei) and the ALDDFT, which is a rudimentary structure in many horses. The transducer must be slightly medial to midline for complete examination of the DDFT. The SDFT can be assessed from the plantar midline. The origin of the SL can be somewhat confusing on ultrasound images, and this may create a dilemma in detecting subtle injury. The SL is firmly attached to the third metatarsal bone (MtIII) (approximately 4- to 5-cm entheses) and

Fig. 16-29 • Transverse ultrasonographic images of zone 2B, 23 cm distal to the tuber calcanei, obtained using a standoff pad. DDFT, Deep digital flexor tendon; ICL, accessory ligament of the DDFT; SDFT, superficial digital flexor tendon; SL, suspensory ligament.

rapidly increases in size from plantar to dorsal within zone 2A. Therefore care must be taken when measuring comparative CSAs to do so at exactly the same level within zone 2A. In longitudinal images the origin of the SL often does not have a tight parallel fiber pattern, which results in an FAS of 1. The large bony surfaces of the second metatarsal bone (MtII) and the MtIV obstruct a clear view, and often a linear anechoic artifact is created by more superficial blood vessels. The origin of the SL begins slightly lateral to midline and thus is not parallel to the plantar surface of the MtIII. The SL appears rhomboid from the plantar midline, but if viewed from slightly medial of midline, it appears more rectangular. CSA measurements should be obtained from one view or the other, but not mixed. Comparison of the longitudinal and transverse views of the SL may help in identifying the plantar and dorsal borders.

Zone 2B

Hindlimb zone 2B extends approximately 21 to 24 cm distal to the tuber calcanei. The SDFT, DDFT, ALDDFT, and SL can be viewed adequately from a midline and slightly medial positioning of the transducer (Figure 16-29). At this level the SDFT is slightly crescent shaped, and the DDFT is ovoid and slightly medially placed. The ALDDFT is visible on the dorsal border of the DDFT. The SL is roughly rectangular with an apex toward the plantar lateral aspect (Figure 16-30). No unique anatomical features identify this zone; it is identified only by measurement.

Zone 3A

Zone 3A ranges from 24 to 32 cm distal to the tuber calcanei. The SDFT is slightly crescent-shaped and is positioned directly over the DDFT. The SL at this level is roughly rectangular with an apex on the plantar lateral border. Zone 3A has no unique anatomical features.

Zone 3B

Hindlimb zone 3B extends from 28 to 32 cm distal to the tuber calcanei. The SDFT is crescent shaped and narrower

Fig. 16-30 • Transverse (left) and longitudinal (right) ultrasonographic images of zone 2B obtained without a standoff pad. The suspensory ligament (SL) is located between the large oblique arrows. DDFT, Deep digital flexor tendon; MT₃, plantar border of third metatarsal bone; SDFT, superficial digital flexor tendon.

Fig. 16-31 • Transverse ultrasonographic images from zone 4A, 35 cm distal to the tuber calcanei. There is an artifactual hypoechoic zone between the dorsal aspect of the deep digital flexor tendon (DDFT) and the plantar border of the accessory ligament of the DDFT insertion (horizontal arrows). MT₃, Plantar border of third metatarsal bone; SDFT, superficial digital flexor tendon; SL, suspensory ligament.

in the plantar-to-dorsal plane and wider in a medial-to-lateral plane, whereas the DDFT is ovoid. This zone has no unique anatomical features.

Zone 4A

Hindlimb zone 4A extends from 32 to 36 cm distal to the tuber calcanei. In this zone the ALDDFT inserts into the DDFT, and a normal hypoechoic artifact may be seen on the dorsal border of the DDFT (Figure 16-31). This is the most distal zone in which the SL is a single unit. The proximal aspect of the DFTs may be seen.

Zone 4B

Hindlimb zone 4B extends from 36 to 43 cm distal to the tuber calcanei and has the same anatomical features as forelimb zone 3B. The hindlimb branches of the SL tend to be longer (approximately 10 cm) and a little larger than the forelimb branches.

Zone 4C

Zone 4C extends from 43 to 47 cm distal to the tuber calcanei and has the same anatomical features as forelimb zone 3C.

Palmar and Plantar Pastern Zones and Descriptions

Qualitative assessments are more critical in pastern ultrasonography because some lesions are not accompanied by clinically significant changes in CSA. If DFTS tenosynovitis is coupled with a subtle primary tendon injury, the tendon may be mildly enlarged. Marginal longitudinal tears of the DDFT require precise qualitative inspection of the lateral and medial borders of the DDFT and the vincula. Fibrous adhesions of the sheath may be identified but may not be accompanied by an increase in DDFT CSA.¹⁹ It also is more difficult to obtain accurate FAS for the branches of the SDFT and oblique sesamoidean ligament (or middle distal sesamoidean ligament). The distal metacarpal or metatarsal regions should also be examined when assessing the DFTS in the pastern.

The pastern is a complex anatomical structure including many ligaments, joint recesses, vasculature, fibrocartilaginous insertional attachments, entheses, joint surfaces, and two major tendons.²⁰ The major structures of practical and common clinical concern are the DFTS, SDFT and branches, DDFT, oblique sesamoidean ligament (middle distal sesamoidean ligament), and straight sesamoidean ligament (or superficial distal sesamoidean ligament). The pastern can be arbitrarily divided into four zones, each with unique anatomical features. The pastern is divided into three palmar or plantar zones along the proximal phalanx (P1) and one zone at the proximal interphalangeal joint (Figure 16-32).

Fig. 16-32 • Ultrasonographic zone designations for the pastern. See text for zone descriptions.

Pastern Zone Designations and Descriptions

Zone P1A

Zone P1A extends approximately 1 to 3 cm from the base of the ergot. Anatomical landmarks, such as the ergot, can be used to identify this zone. The SDFT is viewed from the midline and is a crescent-shaped, single-unit structure with very slight enlargement and rounding of the medial and lateral borders. The entire SDFT is included for CSA data. The palmar or plantar surface of the SDFT is covered by the thin proximal digital annular ligament. Dorsal to the SDFT on the midline view lies the ovoid DDFT. Anechoic fluid in the DFTS is interposed between the DDFT and the triangular straight sesamoidean ligament. Occasionally a fibrous bridge of the oblique sesamoidean ligament or a small portion of the cruciate sesamoidean ligament (or deep distal sesamoidean ligament) may be identified dorsal to the straight sesamoidean ligament. Dorsal to the SDFT on the midline view is a hypoechogenic or anechogenic rounded joint recess of the metacarpophalangeal or metatarsophalangeal joint. The medial and lateral origins of the oblique sesamoidean ligament are seen as two distinctly separate structures and are more adequately viewed by medial and lateral parasagittal placement of the transducer.

Zone P1B

Zone P1B extends from 3 to 5 cm distal to the base of the ergot (Figure 16-33). The SDFT is still a single unit starting to form rounded medial and lateral branches, which are evaluated by moving the transducer medially and laterally. The DDFT has a bilobed appearance, and unless the transducer is perpendicular to the DDFT, central hypoechoic areas are seen in each lobe. The DFTS is seen on the dorsal surface of the DDFT, dorsal to which is the square or rectangular straight sesamoidean ligament. The oblique sesamoidean ligament is seen as a single structure in close

Fig. 16-33 • Transverse ultrasonographic images of zone P1B obtained using a standoff pad. The left image targets the superficial digital flexor tendon (SDFT). The right image targets the deep digital flexor tendon (DDFT), straight sesamoidean ligament (SDSL), and middle distal sesamoidean ligament or oblique sesamoidean ligament (MDSL). P₁, Palmar border of the proximal phalanx.

Fig. 16-34 • Transverse (*left*) and longitudinal (*right*) ultrasonographic images of zone P1C obtained using a standoff pad. The oblique arrows indicate the untargeted medial and lateral branches of the superficial digital flexor tendon. The vertical arrow indicates the insertion of the middle distal sesamoidean ligament (MDSL). DDFT, Deep digital flexor tendon; P₁, palmar border of the proximal phalanx.

proximity to the palmar or plantar surface of P₁, dorsal to the straight sesamoidean ligament.

Zone P1C

Zone P1C extends approximately 5 to 7 cm distal to the base of the ergot (Figure 16-34). The bilobed DDFT lies subcutaneously. The square or slightly rectangular straight sesamoidean ligament is on the dorsal surface of the DDFT. The oblique sesamoidean ligament is not visible because zone P1C is distal to its insertion. The teardrop-shaped medial and lateral branches of the SDFT are viewed by moving the transducer medially and laterally.

Zone P2A

Zone P2A extends approximately 6 to 9 cm distal to the base of the ergot. A thin distal digital annular ligament is closely associated with the palmar or plantar border of the DDFT. The DDFT has a bilobed appearance but is narrower from palmar or plantar to dorsal and wider from medial to lateral. Deep to the DDFT is the middle scutum, the fibrocartilaginous insertion of the straight sesamoidean ligament, which may have a heterogeneous echogenicity (Figure 16-35). Deep to the middle scutum is the proximal interphalangeal joint recess. The medial and lateral branches of the SDFT insert onto the distal aspect of the proximal phalanx and the proximal eminence of the middle phalanx.

Ultrasonography of Proximal Parts of the Limbs

Quantitative ultrasonographic evaluation can be applied to other anatomical areas and the lower limb areas described. These areas do not have zonal designations, and all are identified by measurement from a bony eminence. Many structures contain some muscle fiber bundles that are hypoechogenic, which makes detection of lesions more difficult. Whenever possible, we compare echogenicity, fiber alignment, and CSA between the limbs to

Fig. 16-35 • Transverse (*left*) and longitudinal (*right*) ultrasonographic images of zone P2A obtained using a standoff pad. DDFT, Deep digital flexor tendon; P₁, palmar border of the proximal phalanx; P₂, the palmar border of the middle phalanx; SDSL, superficial distal sesamoidean ligament or straight sesamoidean ligament; SM, scutum medium.

determine some quantitative data to support a qualitative diagnosis.

CLINICAL ULTRASONOGRAPHY

With these suggested fundamental principles in terminology and a systematic concept of data collection, the clinician is prepared to examine the horse. A 7-year-old TB gelding racehorse that had raced for 5 years, with 80 lifetime starts, 14 wins, and \$74,568 in earnings, raced poorly 4 days previously. The next day, the trainer noted peritendinous swelling but no lameness. The horse had never had swelling in this area previously. The horse had received 2 g of phenylbutazone intravenously 24 hours before the race and 2 g immediately after the race. There was heat, slight subcutaneous swelling, and sensitivity and slight enlargement of the SDFT. A core lesion of the SDFT was detected ultrasonographically (Figure 16-36). This scenario raises several questions. How serious is the injury? Can the horse be treated symptomatically and continue to race? If the horse is rested, will it be able to race again? If the horse is rested, which therapy should be used? How will the degree of healing be determined? Each horse is assessed by subjective evaluation of the ultrasonographic images and quantitative analysis.

Quantitative Analysis

The weakest link, or maximal injured zone, is the level at which the biggest proportion of tendon CSA is reduced in echogenicity, or the zone with the largest increase in CSA when compared with a normal contralateral limb. Total structural size is obtained by summing the CSA from each zone. To obtain the percentage of total extent of injury, add the lesion CSA from all levels with a lesion. The total lesion CSA is divided by the total structure CSA and multiplied by 100. The resulting number provides an estimate of structural compromise. It is this percent of total lesion

Fig. 16-36 • Transverse (left) and longitudinal (right) ultrasonographic images from zone 3A obtained using a standoff pad. The vertical arrow indicates a type 3 core lesion of the superficial digital flexor tendon (SDFT). The horizontal arrow indicates the target path on the longitudinal image, with a fiber alignment score of 3 (FAS-3). DDFT, Deep digital flexor tendon; ES-3, echo score 3; SL, suspensory ligament.

(% T-lesion) that is used to categorize injury and relates the severity of structural injury to the client.

Quantitative Terms

The following terms are used in reference to injuries:

1. Maximal injury zone (MIZ)
2. Maximal injury zone cross-sectional area (MIZ-CSA)
3. Maximal injury zone lesion cross-sectional area (MIZ-LCA)
4. Maximal injury zone type or echo score (MIZ-TS) (MIZ-ES)
5. Maximal injury zone fiber alignment score (MIZ-FAS)
6. Total cross-sectional area (sum of included levels; T-CSA)
7. Total lesion cross-sectional area (sum of all levels with a lesion; TL-CSA)
8. Total type or echo score (sum of all levels with a score; T-TS or T-ES)
9. Total fiber alignment score (sum of all level scores; T-FAS)
10. Average fiber alignment score (total divided by number of levels included; A-FAS)
11. Percent total lesion: $[(TL-CSA \div T-CSA) \times 100 = \% \text{ T-lesion}]$

In a normal horse, typical measurements of T-CSA in the forelimb include the following:

- 8 zones of the SDFT = 886 mm²
- 8 zones of the DDFT = 1001 mm²
- 5 zones of the ALDDFT = 449 mm²
- 11 zones of the SL = 1156 mm²
Main body of the SL (5 zones) = 614 mm²
Lateral branch (3 zones) = 258 mm²
Medial branch (3 zones) = 284 mm²

We find that this quantitative assessment provides practical, useful information that can be used routinely and that lesions can be placed in one of six categories.

Lesion Categories

Category I

Category I implies no substantial qualitative or quantitative abnormality. No tendon or ligament fiber bundle lesions are detected, and all zones have lesion and FASs of zero. No single zone has a CSA measurement greater than 39% compared with the contralateral limb. This percentage of tolerance more than adequately allows for method error, especially in zones 1A and 3A. However, with precise technique, a variation greater than 25% indicates substantial structural enlargement. Assessment of T-CSA depends on the number of zones included. The larger the number of zones included, the less difference there should be between limbs:

- 6/7 zones: <15%
- 11 zones: <12%
- 5 zones: <17%
- 3 zones: <20%
- 2 zones: <25%

A 9-year-old TB mare competing as a hunter developed new swelling in the right proximal metacarpal region and slight, intermittent lameness. The client was concerned that the tendon was injured, and if so, did not want to continue athletic use of the horse, which would risk further injury. Palpation revealed swelling (2/5), increased skin temperature (2/5), and a painful response to direct digital pressure of the proximal aspect of the right fore SDFT. Both forelimbs were examined ultrasonographically. No qualitative abnormalities were detected in the normal limb. Subcutaneous fluid was accumulated in the affected limb, indicating edema with or without hemorrhage, but echogenicity of the SDFT was normal. CSA was measured for seven zones of each limb. Zone 1B was determined the maximal injured zone, and the CSA of the SDFT was 25% larger than the normal limb (i.e., category I) but suggestive of tendon enlargement. The T-CSA difference was only 3%. The SDFT was considered normal, although two zones had slightly enlarged CSA (1B was +25% and 2A was +23%). It was recommended that exercise be restricted to walk and trot for 7 days with daily icing, daily bandaging with alcohol and thick standing bandages be used, and phenylbutazone (2 g once daily for 5 days) be administered. If the swelling was 100% reduced after this time, then the horse could return to normal athletic use. If no improvement occurred within 7 days or return to work caused a relapse, repeat ultrasonographic evaluation would be indicated. This horse returned to normal use.

Category II

No hypoechoic or anechoic lesions are detectable, but the affected limb has MIZ-CSA measurements greater than 39%, with or without T-CSA for six or seven zones greater than 14% of the normal limb (i.e., measurable focal or diffuse thickening of the tendon or ligament). Causes of category II injuries may include an unusual developmental difference, a new low-grade tendonitis or desmitis, or an older, currently stable healed tendon or ligament injury. Although generalized thickening may not cause great concern initially, there is evidence that continued use will eventually lead to greater injury. For example, 29% of TB racehorses (n = 13) that continued to train and race with a new category II SDFT injury eventually developed a clinically bowed tendon.²¹

Fig. 16-37 • Transverse (left) and longitudinal (right) ultrasonographic images of zone 2B obtained using a standoff pad. The arrows indicate subcutaneous fluid accumulation. CS, Carpal sheath; DDFT, deep digital flexor tendon; ICL, accessory ligament of the DDFT; SL, suspensory ligament.

A 12-year-old TB gelding competing cross-country had recurrent swelling of the SDFT in the midmetacarpal region that reduced with rest and antiinflammatory treatment but returned if work was resumed. The horse had a long toe and was shod in smooth-toed, heavy steel shoes. There was slight, diffuse thickening (2/5) of the SDFT with increased skin temperature and marked sensitivity to direct digital pressure in zone 2B (4/5). Ultrasonographic examination revealed subcutaneous fluid and possible SDFT enlargement (Figure 16-37) in zone 2B. Inflammation of the communicating branch of the palmar nerves was noted, indicating a malpositioned bandage. However, quantitative evaluation indicated a substantial generalized tendon thickening, which is unusual for a focal bandage pinch. The T-CSA was 15% larger than the normal limb (i.e., category II). It was recommended that exercise be restricted to walking with little trotting under saddle for 3 to 4 days a week for 1 month with daily icing and use of a thick stall bandage with alcohol. Foot length was to be shortened and the horse shod with a fully grooved or creased, lighter steel shoe to decrease the strain on the tendon. Five weeks later marked clinical improvement was noted. Ultrasonographic examination revealed that the subcutaneous fluid accumulation had resolved with no qualitative abnormalities of the SDFT. Substantial reduction in the T-CSA measurements indicated a resolution of intratendonous inflammation. These findings add credence to the initial diagnosis of low-grade tendonitis. It is difficult to make this diagnosis qualitatively with any confidence. Only use of quantitative analytical techniques allows the clinician to truly appreciate these changes and be confident in a category II diagnosis.

Category III

In category III lesions, type 1 or 2 focal hypoechogenic fibers bundles are present, with or without clinically significant MIZ-CSA or T-CSA enlargement. To qualify as a category III lesion, the T-TS (T-ES) cannot exceed 3 (i.e., <

2). This abnormality may be an incidental finding, represent minimal tendon or ligament injury, or be the end result of a healed and clinically stable tendon or ligament injury. In these horses, clinical history, physical examination, and serial monitoring help to determine the clinical significance of the ultrasonographic abnormalities.

A 16-year-old Trakehner gelding, used for upper-level dressage, was examined to assess healing of desmitis of the ALDDFT. The horse had been in controlled exercise for many months, and the client was anticipating a progressive return to normal athletic use, assuming the ultrasonographic findings were favorable. Moderate thickening of the ALDDFT (3/5) was confirmed ultrasonographically, including a focal area of compromised fiber bundles along the dorsal lateral border of zone 2A (TS = 1), and a generalized alteration in fiber bundle alignment (T-FAS = 4). Given the knowledge that this horse had been rested for many months, a slow return to training was recommended. The ultrasonographic images can be used as a benchmark for evaluation of the stability of the repair as gradual increases in ligament loading commence. The horse eventually returned to upper-level dressage and has been asymptomatic for 2 years.

Even though category II and III injuries do not seem to represent a very serious compromise to a tendon or ligament, they do alert the clinician, trainer, and owner to a subtle problem that requires medical management and that with early diagnosis is more easily managed. If the decision were made to continue athletic use while performing symptomatic therapy, serial ultrasonographic monitoring would be indicated to monitor stability. In this manner, early clinically significant regressions may be detected before overt clinical signs of reinjury occur. These two injury categories are not easily diagnosed with qualitative assessment alone. Quantitative analysis identifies these low-grade abnormalities. However, these two categories often represent a dilemma for a practitioner. The clinical signs are slight, seldom associated with lameness, and often respond quickly to symptomatic therapy. Therefore it is difficult to persuade trainers to rest horses. However, category II and III tendons and ligaments often represent the earliest of ultrasonographically identifiable injury and have the best chance of full recovery with extended rest. Quantitative evidence may help a client appreciate the significance of the injury. Ultimately, regardless of whether the horse is rested or treated symptomatically for a category II or III injury, periodic comparative data will greatly assist a practitioner in advising clients and help the clients to understand the injury.

Category IV

A category IV lesion is characterized by focal hypoechoic or anechoic lesions with the T-S ≥ 3 , with a specific % T-lesion (Table 16-1). The range of % T-lesion to qualify for category IV varies depending on the number of zones included for determining the "total." The MIZ-CSA or T-CSA may or may not be substantially enlarged. Although this category includes a wide range of injuries, it can be used to document slight injury or an important compromise of tendon or ligament fiber bundles.

A 5-year-old TB racehorse gelding had a right fore SDFT injury of 6 months' duration. The horse had been galloping daily (exercise level 5) for 2 weeks, but the last time the

horse galloped, right forelimb lameness and tendon swelling developed. Physical examination revealed slight swelling (1/5), low-grade lameness (2/5), moderate SDFT thickening (3/5), slight sensitivity to direct digital pressure, and localized heat (2/5) of the right forelimb. Ultrasonographic analysis of the right SDFT in zone 3B displayed a large type 3 anechoic core lesion (Figure 16-38). Quantitative data documented a T-CSA of 1243 mm². CSA was 67% larger than the left fore SDFT in zone 3B. In addition, bundles of compromised tendon were noted in six of the seven zones. These localized lesions of mixed echogenicity, mostly type 1, probably were the result of the previous injury. The new injury was localized to zones 3B and 3C, with echo scores of 2 and 3. In this analysis of reinjury, all areas of reduced echogenicity were included in the total lesion summation. Additional measurements include % T-lesion of 12%, T-TS of 11, T-FAS of 8, and A-FAS of 1.1.

Category V

Category V injuries typically have substantial MIZ-CSA or T-CSA enlargement with focal hypoechoic, anechoic, or both types of lesions. T-TS is greater than 3. This category has been arbitrarily associated with moderate tendon or

Fig. 16-39 • Transverse ultrasonographic images of zone 2A obtained using a standoff pad; the clinically abnormal limb is on the left and the clinically normal limb (*non-clin*) is on the right. The left (L) image (lateral to the left) demonstrates a type 2 lateral border lesion of the superficial digital flexor tendon (SDFT; horizontal arrow). Vertical arrows mark the palmar and dorsal borders of the SDFTs. The lateral border of the right (R) forelimb is to the right. DDFT, Deep digital flexor tendon; ICL, accessory ligament of the DDFT; MIZ-ES 2, maximal injury zone type or echo score of 2.

ligament injury. The range of % T-lesion to qualify for category V varies depending on the number of zones included in arriving at the “total” (Table 16-2).

Many horses with category V or VI injuries or reinjuries exhibit lameness in the early stages, but many category III and IV injuries are not associated with lameness.

A 3-year-old STB pacer, colt, developed swelling of the left fore SDFT after racing 1 week earlier and had previously sustained injury as a 2-year-old. The midmetacarpal region was slightly swollen (1/5) with moderate SDFT thickening (3/5), sensitivity to direct digital palpation (2/5), slight heat (1/5), and slight lameness (2/5). Ultrasonographic examination revealed a type 2, focal, hypoechoic lesion in the lateral border of the SDFT in zone 2A (Figure 16-39). Computer analysis of the left fore SDFT documented hypoechoic or anechoic lesions along the lateral border in six of the seven zones (Figure 16-40). Zone 2A was designated the maximal injured zone because it had the lesion with the largest CSA (37%). The MIZ-CSA of 166 mm² was 47% larger than the same zone of the contralateral normal SDFT. T-CSA of the seven zones was 1179 mm², 31% greater than the contralateral SDFT. Additional measurements included T-TS of 11, T-FAS score of 8, and % T-lesion of 22% (i.e., category V). Unlike many newly injured tendons

or ligaments with similar T-TS and T-FAS scores, this reinjured SDFT had a difference in these scores. This may serve as a means to identify newly injured versus reinjured structures ultrasonographically.

Category VI

Category VI injuries have substantial MIZ-CSA or T-CSA enlargement with more extensive hypoechoic or anechoic lesions than category V. The range of % T-lesion to qualify for category VI varies depending on the number of zone used to determine the “total” (Table 16-3).

A 4-year-old TB racehorse gelding developed swelling of the left fore SDFT after a race 6 days earlier. Physical examination revealed slight swelling (2/5), moderate SDFT thickening (3/5), slight sensitivity to direct digital palpation (2/5), slight heat (2/5), and low-grade lameness (2/5). A large type 3 anechoic lesion of the lateral half of the SDFT was seen in zone 2B, the maximal injured zone (MIZ-LCA 92 mm² representing 54% of the tendon CSA). The MIZ-CSA was 114% larger than the contralateral normal zone 2B SDFT (see Figure 16-15). Six of the seven zones had hypoechogenic or anechogenic contiguous fiber bundles, with a 65% increase compared with the contralateral SDFT. T-LCSA was 300 mm², resulting in a 28% T-lesion. T-TS (14) and T-FAS (14) were the same, a common

finding in newly injured tendons, although not acute SL injuries.

Summary

Tendon and ligament injuries can be graded from 1 to 6 to reflect the severity of injury. Advantages of using quantitative assessment in conjunction with clinical findings and qualitative evaluation include the following:

1. Confirmation or addition to a qualitative diagnosis.
2. Improved detection of subtle structural enlargement not accompanied by detectable echogenicity abnormalities, thus reducing interpretive errors.

3. Establishment of an objective means to categorize the severity of an injury, which can be used to determine prognosis for intended use and whether continued use or extended rest is the optimal choice. It also provides baseline information that can be compared with follow-up examination findings.
4. Enhanced veterinary participation in the rehabilitation of a horse with a tendon or ligament injury.
5. Improved client appreciation of the injury and improved compliance with suggested exercise restraint and treatment.
6. Creation of a common ultrasonographic interprofessional language and provision of a valid tool for research purposes to evaluate treatment responses.

Exceptions

As with most attempts to categorize medical injuries, exceptions almost always are possible. The following are three common exceptions to quantitative categorization of tendon and ligament injuries:

1. Diffuse tendonitis or desmitis. This is an uncommon clinical manifestation of SDFT thickening and is seen mostly in 2-year-old TB racehorses and older event horses and show jumpers. The T-CSA measurements indicate substantial enlargement if the contralateral SDFT is normal. However, injury may be bilateral; therefore CSA measurements are compared with normal values for the breed, size, and age of the horse. Two-year-old TB racehorses in training tend to have larger T-CSA values than similar, older horses. In these horses, not only is the SDFT enlarged, but the entire CSA has a subtle reduction in echogenicity that extends through several zones. Although the % T-lesion is high, it does not necessarily indicate severe tendon fiber disruption because the echogenicity score for each zone is type 1 or 2 and the FAS score is 1 or 2. This indicates a diffuse tendonitis with little loss of tensile strength. Given time and restricted exercise, documentation with serial ultrasonography indicates that most 2-year-old horses generally do well (see Figure 16-33).
2. If the SDFT or SL is totally disrupted, fiber bundles in adjacent zones may appear artificially more hypoechoic or anechoic because of the loss of tension in the structure, which is otherwise known as *relaxation effect*.²² Clinically, tension is lost and the structure can be moved medially and laterally with ease. Ultrasonography shows a loss of parallel fiber alignment and a decrease in echogenicity. Measurement of CSA is difficult and can even be decreased at the maximal injured zone (Figure 16-41). The diagnosis of complete rupture of a tendon or ligament is usually readily made clinically.
3. Total collapse of the SL is characterized clinically by an extreme extension of the metacarpophalangeal or metatarsophalangeal joint (4/5 ankle sink), with little swelling or clinically significant thickening of the SL or SL branch, and no sensitivity to direct palpation. Rupture cannot be palpated, and it appears as though the entire suspensory system has lost its cross-links and stretched, although ultrasonography shows little evidence of fiber tearing. Ultrasonographic images do not reflect the severity of the clinical signs.

Fig. 16-41 • Transverse (left) and longitudinal (right) ultrasonographic images of zone 1B obtained with a standoff pad. The borders of the superficial digital flexor tendon (SDFT) are not defined, and most of the echoes present represent hematoma. The SDFT was completely ruptured. DDFT, Deep digital flexor tendon; ICL, accessory ligament of the DDFT; SL, suspensory ligament.

CLINICAL APPLICATIONS

If clinical evidence of swelling or thickening, with or without lameness, is present, the basic objective of an ultrasonographic evaluation is to determine the cause. Every effort must be made to determine whether tendons and ligaments are normal or abnormal and whether the lameness can be directly attributed to a soft tissue abnormality. Lameness may be visible only at high speeds in a racehorse or during special gait movements in a high-level dressage horse. In some instances the ultrasonographic data are insufficient to confirm the suspected cause, especially in subtle injury, although thorough evaluation and serial ultrasonographic examinations may provide clues.

Incidental abnormalities may be identified that have no bearing on the lameness or represent old, stable injuries of no clinical significance. Careful identification of these abnormalities and serial ultrasonographic monitoring may determine their clinical significance. Sometimes other imaging techniques, such as radiography, nuclear scintigraphy, or MRI, also are required to completely characterize an injury process. For example, evaluation of SL insertion injuries should also include radiological assessment.

Timing of Ultrasonographic Examinations: When to Scan

Timing of the initial ultrasonographic examination is critical. A clinician may be requested to examine a limb within hours of an injury. Peritendinous edema may obscure fiber damage because of acoustic enhancement, and the continued release of destructive enzymes may result in further ongoing fiber injury. Thus an examination shortly after an injury may not reveal the true extent of fiber damage. Ideally, an ultrasonographic evaluation should be delayed until at least 48 to 72 hours after the injury. If an ultrasonographic examination is performed before this time, the

time after injury should be recorded, exercise restricted to walking, and symptomatic therapy instituted. Physical and ultrasonographic evaluations should be repeated after an additional 72 hours.

Clinically significant hypoechoic, anechoic, or both types of lesions may be seen in an injury less than 72 hours old. The areas of reduced echogenicity may represent a combination of hemorrhage (seroma), edema, and fiber bundle injury. The diagnostic dilemma at this stage is that the clinician cannot accurately determine the relative contribution of each. It should not necessarily be assumed that the hypoechogenic areas only represent fiber bundle injury. In most horses this assumption is true, but not always. We administer symptomatic antiinflammatory treatment and advise complete stall rest (exercise level 0) or limited hand walking (exercise level 1A) for 14 to 30 days, followed by an ultrasonographic reevaluation. (The exception to this advice would be if tendon splitting surgery were the treatment of choice to attempt to decompress a core lesion.) When the horse is reexamined, persistent hypoechogenic areas represent fiber bundle compromise, because most inflammatory edema and hemorrhage will have resolved. The severity of the injury can now be determined, and we refer to this as the *baseline evaluation*. The baseline evaluation often reveals the same or increased severity of injury compared with the initial scan (especially in core lesions caused by enzymatic degradation of damaged fiber bundles or pressure necrosis).

As an example, we can compare ultrasonographic images of a SDFT injury after 24 hours and after 22 days. The initial examination determined that the SDFT was 32% larger than the normal contralateral limb and had a 17% T-lesion (category V), a T-TS of 17, and a T-FAS of 16. After symptomatic therapy and a reduction of exercise to exercise level 1A, the baseline scans (22 days later) revealed a 12% increase in size of the SDFT compared with the normal limb, a 13% T-lesion (now category IV), a T-TS of 10, and a T-FAS of 12. The apparent decrease in severity was from resolution of the inflammatory response and absorption of the seroma. The baseline data represent the actual severity of fiber bundle compromise and serve as the starting point for rendering prognosis for intended use, treatment programs, and long-term rehabilitation exercise regimens.

Serial Ultrasonographic Examinations as Part of Case Management

Serial ultrasonographic examinations are best performed when it is anticipated that the exercise level may be increased. This justifies the examination to an owner or trainer. In addition to the ultrasonographic assessment, a clinician must always consider the physiological principles of tendon and ligament healing and the necessary physiological time for healing for the severity of an injury before advising exercise level increases. With time and as quantitative ultrasonographic analysis is more commonly used to evaluate tendon and ligament repair, more definitive recommendations will develop concerning convalescent time based on the severity and location of an injury and the intended athletic function of the horse. The same applies to the quality of the repair. Horses destined for light work will be able to perform with a less than perfect repair, but

racehorses and other high-level athletes will require optimal repair and a reasonable time to give the best chance for return to athletic use without reinjury.

During rehabilitation a qualitative ultrasonographic evaluation of the clinically injured tendon is done to detect obvious lesions, evidence of reinjury, restricting peritendinous tendon sheath fibrosis, or restriction by the PAL. Objective, or quantitative, ultrasonographic assessments should also be determined. Guidelines for an optimum chance to return to racing include the following²³:

1. At least a 60% decrease in category IV % T-lesion and <12% total lesion cross-sectional surface area (T-LCSA) for all categories of severity of injury.
2. At least a 10% to 15% decrease in T-CSA from baseline for all categories of injury (a relatively greater decrease in more seriously injured tendons).
3. At least a 70% decrease in the T-TS (ideally <4; the closer to 0, the better).
4. At least a 75% decrease in the T-FAS (ideally <4; the closer to 0, the better) before advancing to exercise level 5.
5. The horse should meet at least three of the above requirements with only minimal failure of the other criterion.

Nonetheless, even a perfectly healed tendon or ligament injury can be reinjured. Reinjury is especially common in TB racehorses. However, if the repair is of poor quality, reinjury is likely, and these horses should be held back from active training until healing has improved. Decision making is more accurate when it is based on ultrasonographic evaluation and consideration of necessary physiological time for intended use than when relying on clinical inspection.

The advantages of veterinary intervention and using quantitative ultrasonographic parameters in case management provide a means to optimize the chances of returning an injured horse to athletic usefulness and are reviewed in this clinical example. A 4-year-old TB racehorse with a left fore SDFT injury was examined 3 days after a race. The maximal injured zone was zone 2B (59% lesion), T-CSA was 1206 mm², T-TS was 11, and T-FAS was 16. This was a 49% T-lesion (i.e., category VI). The horse was treated with a series of three external blisters and 6 months' pasture rest, a typical theory in the early 1990s. The horse was reassessed 8 months after injury to determine whether it could return to training (exercise level 5). The tendon was tight and cold. Qualitative ultrasonographic examination indicated improvement, although abnormalities persisted, which were interpreted to be the end result of repair. Thus the trainer was wrongly advised to return to training.

In light of current knowledge, the ultrasonographic data at the time of reevaluation provided clear indication of an unstable repair. The T-CSA had increased 15% and % T-lesion decreased by only 50%, and therefore was still quite high at 22%. In addition, neither T-TS nor T-FAS met a target decrease of 75%. After 4 weeks of galloping, the horse worked at race speed (breezed) once and became lame again. An ultrasonographic evaluation identified extensive reinjury to the same tendon (i.e., category VI). Thus quantitative analysis of injuries is an extremely beneficial tool to monitor progress of tendon healing.

Chapter 17

Ultrasonographic Examination of Joints

Jean-Marie Denoix

Ultrasonography has become an essential imaging technique for assessing joint lesions.¹⁻⁶ It provides information complementary to radiography but does have some limitations. Ultrasonography requires a precise knowledge of anatomy, not only bone anatomy,⁴ and a systematic approach. Examining the joints of the distal part of the limb is physically uncomfortable for the imager and is time-consuming: complete examination of a joint may take up to 30 minutes. Quick examination of joints requires several years of daily practice.

The indications for ultrasonographic examination of equine joints include synovial fluid distention, local swelling, pain on passive manipulation of the joint, improvement in lameness after intraarticular or perineural analgesia, and positive radiological or scintigraphic findings. The area to be examined should be clipped, not shaved, and washed with hot water. High-resolution transducers (7.5- to 13-MHz linear probes) and a standoff pad are used for superficial structures. Convex array 2.5- to 5-MHz transducers are preferable for deeper structures. Both left and right joints should be examined to improve sensitivity and specificity. The image quality depends not only on the frequency of the transducer but also on the quality of the machine (from treatment of the signal to display on the monitor) and the skill of the operator in placing and orienting the transducer.

A comprehensive description of all joints cannot be given in this book. The fetlock joint is a model for a general approach to ultrasonography of joints because of its simple anatomy. Some aspects of examination of the stifle and hock also are presented.

FETLOCK

Each aspect of the joint should be examined systematically using 7.5- to 13-MHz linear transducers and a thin standoff pad.

Dorsal Aspect

Figure 17-1 shows normal ultrasonographic anatomy.^{4,5} In normal fetlock joints the articular capsule is echogenic (except if too relaxed), and the articular margins of the proximal phalanx and the condyles of the third metacarpal bone (McIII) are smooth.

Ultrasonography is a useful technique for the differential diagnosis of soft tissue injuries on the dorsal aspect of the fetlock joint. These lesions include subcutaneous swelling or abscess, bursitis of the subtendonous bursa of the extensor tendons, extensor tendonitis, capsulitis, synovial

fluid distention of the dorsal recess of the metacarpophalangeal joint (Figure 17-2), and chronic proliferative synovitis of the proximodorsal synovial fold of this joint (Figure 17-3). Thinning, fibrillation, and fissures of the articular cartilage of the dorsal and distal aspects of the condyle of the McIII can be identified with high-resolution transducers. Subchondral bone lesions can sometimes be detected before they are visible radiologically. Ultrasonography may

Fig. 17-1 • Sagittal ultrasonographic image of the dorsal aspect of the fetlock, normal appearance. Proximal is to the left. 1, Skin; 2, dorsal joint capsule; 3, proximal synovial fold; 4, subchondral bone of the condyle of the third metacarpal bone; 5, articular cartilage of the condyle of third metacarpal bone; 6, proximal phalanx.

Fig. 17-2 • Sagittal ultrasonographic image of the dorsal aspect of the fetlock joint. An abnormal synovial fluid accumulation appears between the joint capsule and the articular surface. The diagnosis is synovial fluid effusion, indicative of synovitis. Proximal is to the left. 1, Skin; 2, dorsal joint capsule; 3, proximal synovial fold; 4, subchondral bone of the condyle of the third metacarpal bone; 5, articular cartilage of the condyle of the third metacarpal bone; 6, synovial fluid; 7, proximal phalanx.

Fig. 17-3 • Sagittal ultrasonographic image of the dorsal aspect of the fetlock joint. An abnormal hypoechoogenic mass appears between the capsule and the condyle of the third metacarpal bone. The proximal aspect of this condyle is irregular, indicating bone lysis (*arrowhead*). The diagnosis is chronic proliferative synovitis. 1, Skin; 2, dorsal joint capsule; 3, proximal synovial fold tremendously thickened and echogenic; 4, condyle of the third metacarpal bone; 5, synovial fluid.

be more sensitive than radiography for detection of the site and number of osteochondral fragments.⁷

Dorsomedial and Dorsolateral Aspects

Examination of the dorsomedial and dorsolateral aspects of the joint is especially useful for complete evaluation of the articular margins, which are smooth in a normal joint. The most common abnormal finding is the presence of periarticular osteophytes. Other injuries are subcutaneous lesions (fibrosis, swelling) and capsulitis.

Medial and Lateral Aspects

The medial and lateral collateral ligaments have superficial and deep layers.⁴ If the transducer is parallel to the skin (the ultrasound beam is perpendicular to fiber interface), the superficial layer of the collateral ligament is echogenic and the deep layer is hypoechogenic. Either layer may be damaged (*Figure 17-4*). If both layers are affected, joint instability, subluxation, or luxation occurs.

Palmar Aspect

A normal fetlock joint has a small amount of anechogenic synovial fluid in the proximopalmar recess of the fetlock joint. Abnormal findings observed in affected horses include

Fig. 17-4 • **A**, Physical appearance of an injured right hind fetlock joint (arrowheads show medial enlargement). Radiography found no bony abnormalities. **B**, Transverse ultrasonographic images of the lateral (*L*) and medial (*M*) aspects of the injured fetlock. The size and architecture differ greatly between the normal lateral collateral ligament and the injured medial ligament. **C**, Longitudinal ultrasonographic image of the medial aspect of the fetlock shows the thickening and architectural alterations of the medial collateral ligament. The diagnosis is chronic desmopathy of the medial collateral ligament. 1, Skin; 2, collateral ligament; 3, condyle of the third metatarsal bone.

Fig. 17-5 • Longitudinal ultrasonographic image of the palmarolateral aspect of the fetlock demonstrating a marked fluid distention of the palmaroproximal recess of the fetlock. The diagnosis is synovial fluid effusion indicative of synovitis. 1, Skin; 2, synovial fluid; 3, synovial membrane and villi.

synovial fluid distention, often associated with enlarged synovial folds, indicative of synovitis (Figure 17-5).

Echogenic material may be observed in the synovial fluid in any view. Small echogenic spots may represent fibrin or cartilaginous debris. Larger echogenic masses are compatible with osteochondral fragments. These abnormal findings are more easily seen after movement of the joint. A homogeneous increase in echogenicity of the fluid is compatible with hemarthrosis or infectious synovitis.

STIFLE

Ultrasonography has considerably improved the knowledge and the diagnosis of soft tissue injuries of the femoropatellar and femorotibial joints.

Femoropatellar Joint

The femoropatellar joint is examined using 5- to 10-MHz linear transducers with a thin standoff pad. The normal patellar ligaments are homogeneously echogenic.¹⁻³ The articular cartilage is thicker over the lateral trochlear ridge compared with the medial. Each femoral trochlea has a regular hyperechogenic subchondral bone surface.

Medial patellar desmopathy usually is iatrogenic (i.e., caused by medial patellar desmotomy or desmoplasty). Desmopathy of the intermediate (middle) patellar ligament is an injury that occurs in athletic horses.⁸ Lateral patellar desmopathy often is caused by trauma (Figure 17-6).

Osteochondrosis of the trochlear ridges is easy to diagnose, and ultrasonography provides information on the extent of the lesion (especially in a lateromedial direction), the size and location of the osteochondral fragments, and the severity of alteration of the subchondral bone.⁹ Evaluation of the synovial fluid and membrane may also be useful to assess the consequences of ligamentous and osteochondral lesions in the joint.

Medial and Lateral Femorotibial Joints

Examination of the femorotibial joint requires 5- to 10-MHz linear transducers and a thin standoff pad.¹⁰⁻¹³ In normal joints the medial recess of the medial femorotibial joint is less than 3 cm long in a craniocaudal direction, and the

Fig. 17-6 • Longitudinal ultrasonographic image of the lateral patellar ligament demonstrating localized enlargement. At the site of the lesion (arrowheads) the ligament is hypoechoic and shows severe architectural changes. Diagnosis is traumatic lateral patellar desmopathy. 1, Skin; 2, lateral patellar ligament; 3, lateral ridge of the femoral trochlea (subchondral bone surface); 4, patella.

Fig. 17-7 • Transverse ultrasonographic image of the medial recess of the medial femorotibial joint. Anechoic synovial fluid has distended this recess. The diagnosis is synovial effusion compatible with synovitis and other potential injuries of the femorotibial joint. 1, Skin; 2, medial femoral fascia; 3, synovial membrane; 4, medial recess of the medial femorotibial joint; 5, medial aspect of the distal femur.

synovial fluid is totally anechoic. The normal medial collateral ligament and medial meniscus are homogeneously echogenic,¹⁻³ provided that the ultrasound beam is perpendicular to the orientation of the fibers. The normal articular margins of the medial femoral condyle and tibial plateau are smooth and regular.

The medial recess of the medial femorotibial joint can be considered a mirror of the joint, because its size and content are influenced by all joint lesions. Abnormalities include synovial effusion (Figure 17-7); chronic

Fig. 17-8 • Transverse ultrasonographic image of the medial recess of the medial femorotibial joint. Echogenic material distends the recess. The diagnosis is hemarthrosis compatible with other potential ligament or bone injuries of the femorotibial joint. 1, Skin; 2, medial femoral fascia; 3, medial recess of the medial femorotibial joint; 4, medial aspect of the distal femur.

Fig. 17-9 • Longitudinal ultrasonographic image of the medial recess of the medial femorotibial joint. Echogenic material floats in the synovial fluid. These echogenic spots represent fibrin, cartilaginous debris, or meniscal debris. Proximal is to the right. 1, Skin; 2, medial femoral fascia; 3, medial recess of the medial femorotibial joint; 4, medial femoral condyle; 5, medial meniscus (anechogenic because of the orientation of the ultrasound beam).

proliferative synovitis; hemarthrosis (Figure 17-8); echogenic spots compatible with fibrin, cartilaginous, or meniscal debris (Figure 17-9); osteochondral fragments; and calcinosis circumscripta. The caudal recess of the medial femorotibial joint can be examined with 2.5- to 5-MHz sector or convex array probes. Distention of this recess always indicates severe femorotibial disease. Distention of the subextensorius recess on the craniolateral aspect of the lateral femorotibial joint can be observed in

Fig. 17-10 • **A**, Longitudinal ultrasonographic image (proximal is left) of the medial collateral ligament of the femorotibial joint. This ligament is enlarged and hypoechoic (arrowheads). Diagnosis is traumatic medial collateral desmopathy. **B**, Transverse ultrasound scan of the medial collateral ligament. 1, Skin; 2, medial collateral ligament; 3, medial meniscus; 4, medial femoral condyle.

lateral femorotibial arthropathy or femoropatellar joint lesions.

Desmopathy of the medial collateral ligament may be identified as disruption in the normal parallel fiber pattern (Figure 17-10).

Meniscal injuries can be observed alone or with other ligamentous or bone injuries (Figure 17-11). In horses, approximately 75% of these lesions are found in the medial meniscus and 25% in the lateral meniscus. A wide range of type and severity of meniscal injuries may be seen (see Figures 17-11 and 17-12).

If a transducer is held vertically and moved in a caudo-cranial direction, complete examination of the articular margins of the femoral condyles is possible. Ultrasonography may be more sensitive than radiography in detecting periarticular osteophytes. If the stifle is examined in flexion, the cartilage and subchondral bone surface of the femoral condyles can be imaged.¹⁻³ Alterations of the subchondral bone surface and echogenicity may be detected.

Fig. 17-11 • Proximodistal ultrasonographic image of the medial aspect of the medial femorotibial joint showing a transverse section of the body of the medial meniscus. An obvious hypoechoic defect (*arrowheads*) is seen. The diagnosis is medial meniscal lesion. 1, Skin; 2, medial collateral ligament; 3, medial meniscus; 4, medial femoral condyle (with anechoic articular cartilage); 5, medial tibial condyle (with anechogenic articular cartilage).

Fig. 17-12 • **A**, Proximodistal ultrasonographic image of the craniomedial aspect of the medial femorotibial joint showing transverse sections of the cranial horn of the medial meniscus. Hyperechogenic material is present in the deep (axial) part of this horn (*arrowheads*). **B**, Transverse ultrasonographic image of the craniomedial aspect of the medial femorotibial joint showing a horizontal section of the cranial horn of the medial meniscus. This scan confirms presence of hyperechogenic material in the horn. The diagnosis is that hyperechogenic material is a focal site of mineralized metaplasia in a meniscus. 1, Skin; 2, medial femoral fascia; 3, medial meniscus; 3a, cranial attachment; 4, medial femoral condyle; 5, medial tibial condyle.

Fig. 17-13 • A, Acute medial collateral desmopathy in a 15-month-old filly. Physical appearance of the hock with a medial swelling. **B**, Longitudinal ultrasonographic image of the calcanean fasciculus of the medial collateral ligament. This structure is thickened and hypoechoic with evidence of fiber disruption. An echogenic osteochondral fragment (*arrowhead*) appears close to the medial malleolus of the tibia. The diagnosis is severe desmopathy with avulsion fracture involving the calcanean fasciculus of the medial collateral ligament. 1, skin; 2, medial malleolus of the tibia; 3, long medial collateral ligament; 4, short medial collateral ligament—calcanean fasciculus (CALC); 5, medial aspect of the talus (TAL).

Fig. 17-14 • Longitudinal ultrasonographic image of the calcanean fasciculus of the medial collateral ligament of a 9-year-old Three Day Event gelding after injury 3 months previously. This structure (*black arrows*) is thickened and has architectural changes. The diagnosis is desmopathy of the calcanean fasciculus of the medial collateral ligament. 1, Skin; 2, medial malleolus of the tibia; 3, long medial collateral ligament; 4, short medial collateral ligament—calcanean fasciculus (*arrowheads*); 5, medial aspect of the talus.

COLLATERAL LIGAMENTS OF THE HOCK

The causes of soft tissue enlargement of the hock may be difficult to assess clinically and radiologically. The medial and lateral collateral ligaments of the hock are highly echogenic fibrous structures.¹⁴ Each is divided into a long collateral ligament, which inserts distally on the distal aspect of the tarsus and the proximal aspect of the metatarsal region, and a short collateral ligament with two fasciculi: a calcanean fasciculus and a talien one.

Proximal avulsion fracture of the calcanean fasciculus of the medial collateral ligament has been identified (*Figure 17-13*). Lesions of this ligament also can be identified in hocks with no radiological abnormality (*Figure 17-14*). In old lesions the long medial collateral ligament remains thickened and may have focal echogenic sites associated with mineralization.

Several types of injury of the lateral collateral ligament have been identified, including desmopathy of the long lateral collateral ligament, avulsion fracture of the short lateral collateral ligament at the proximal insertion on the lateral malleolus of the tibia (distal portion of the fibula), and desmitis of the short lateral collateral ligament associated with sudden synovial distention of the tarsocrural joint capsule.

Chapter 18

Ultrasonography and Orthopedic (Nonarticular) Disease

Virginia B. Reef

The use of diagnostic ultrasonography for evaluation of tendons, ligaments, tendon sheaths, bursae, and joints is discussed in Chapters 16, 17, and 82, and horse preparation for other musculoskeletal uses is similar.

SKELETAL MUSCLE

Normal skeletal muscle appears heterogeneous, with hypoechogenic muscle fibers laced with and surrounded by echogenic fascia, connective tissue, and fat. In transverse section a normal muscle has a marbled or speckled appearance, which is unique for each individual muscle, as is its striated appearance in longitudinal section.^{1,2} A non-weight-bearing muscle appears more echogenic than the same muscle when the horse is fully weight bearing.^{1,2} Therefore comparisons between contralateral muscles should be made when the horse is bearing weight evenly.

Traumatic muscle injuries, myositis, and masses infiltrating the muscles usually can be differentiated from one another by ultrasonography.¹ Muscle tears in horses most frequently are seen in the hindlimb and shoulder musculature. In neonatal foals, muscle tears are most commonly seen in the hindlimb.³ The affected muscle or muscles can be identified by tracing the involved muscle from its origin to insertion. Fluid-filled anechogenic areas with hypoechogenic loculations are located within the muscle belly, associated with areas of hemorrhage and muscle fiber tearing (Figure 18-1).^{1,3-6} As the muscle injury becomes more severe, large areas of interfascial and subcutaneous hemorrhage are detected. The free edge of a completely disrupted muscle may be imaged floating in the anechogenic loculated fluid in the hematoma. Echogenic areas of clot are often imaged within the intramuscular, interfascial, or subcutaneous hematoma. As these echogenic clots become more organized, they may cast an acoustic shadow from the far surface. Rupture of the gastrocnemius muscle should be considered as a cause of recumbency in neonatal foals that are unable to rise and have soft tissue swelling in the hindlimb. Rupture of the gastrocnemius muscle has been reported as a complication of dystocia.³ Partial muscle tears are more difficult to diagnose because the ultrasonographic abnormalities are more subtle.¹ The normal striated muscle pattern is lost with increased echogenicity of the injured muscle.¹ Swelling of the affected muscle usually is present. Tears in the muscle fascia or thickening of the muscle fascia or fasciitis also may be detected ultrasonographically.¹

Ultrasonography is an excellent tool for monitoring the resolution of the hematoma and the healing of the muscle.^{1,5} The affected horse's exercise should be restricted until the hematoma has resolved and the muscle tear has filled in with tissue. As the muscle heals, the fluid becomes more echogenic and the area fills in. The healing muscle may become more heterogeneous. Hyperechogenic areas of muscle scarring are seen associated with fibrotic myopathy, especially in the semitendinosus (primarily) and semimembranosus muscles, but can also occur in other muscles such as the biceps femoris and gracilis (rare).^{1,5,7} As these areas of fibrosis become more organized, acoustic shadowing from the far side of the fibrotic area may be detected. Hyperechogenic areas casting acoustic shadows are seen in horses with an ossifying myopathy and frequently are found adjacent to areas of fibrotic myopathy.¹ Areas of mineralization develop as scattered, pinpoint hyperechogenic areas that progressively become linear and result in acoustic shadowing from the near side of the areas.

Postanesthetic myopathy results in increased echogenicity of the affected muscle, with loss of the normal muscle striations.^{1,2} Muscle edema may result in the muscle appearing less echogenic than normal if the lesion is evaluated early in the course of the disease. Once a large influx of inflammatory cells has occurred, the affected muscle becomes more echogenic. A necrotizing myositis usually results in a more heterogeneous ultrasonographic appearance associated with the inflammatory cell infiltrate and bacterial infection.¹ Cavitation of a severely affected muscle is associated with liquefactive necrosis. Hyperechoic echoes, associated with the local production of gas by bacteria, may be seen with an anaerobic necrotizing myositis.¹

Muscle tumors are rare; the most common muscle tumor is hemangiosarcoma. Discrete echogenic masses in the muscle or anechogenic loculated, more heterogeneous masses may be detected.¹ Central anechogenic or

Figure 18-1 • Longitudinal ultrasonographic image of a torn semimembranosus muscle showing large, anechogenic fluid-filled areas, hypoechogenic amorphous areas, and more normal striated muscle at the periphery of the images. The anechogenic areas and hypoechogenic amorphous area are consistent with a hematoma replacing the muscle. The anechogenic area is the fluid component of the hematoma, whereas the hypoechogenic areas (arrow) represent the fibrin and clot.

hypoechoic areas representing tumor necrosis are identified in large or rapidly growing tumor masses. Primary muscle tumors such as rhabdomyosarcomas are extremely rare but can be a cause of lameness.⁸ Accurate identification of tumor type in muscle necessitates obtaining an ultrasound-guided biopsy and histopathological evaluation of the tissue obtained.

NERVE

Distinguishing peripheral nerves requires high-resolution images because the majority of nerves are small. Accurate knowledge of the locations of the nerves and the surrounding landmarks is important for identification. The nerves usually are slightly more echogenic than the surrounding soft tissue structures and are round to oval in transverse section.¹ Deep nerves usually appear as two tubular structures with parallel, straight, sharply hyperechogenic borders and a hypoechoic center.⁹ Superficial nerves have linear internal echoes that parallel the straight hyperechogenic borders.^{1,9} Enlargement of the nerve with an increase or decrease in its echogenicity, with or without heterogeneity in its ultrasonographic appearance, is consistent with neuritis,¹ which may be a primary cause of lameness (see Chapter 82).

PENETRATING INJURIES

Ultrasonographic examination may be helpful in assessing penetrating injuries. The examiner should start at the site of the puncture wound and follow the path left by the penetrating object, a hyperechogenic tubular tract extending into the soft tissues.^{10,11} The tract appears hyperechogenic from gas lining the tract. Any foreign material usually is hyperechogenic and casts acoustic shadows in two mutually perpendicular planes. Foreign material is usually irregular in shape, differs in size when imaged in two mutually perpendicular planes, and typically has high acoustic impedance relative to soft tissue. This examination can be done under aseptic surgical conditions when indicated.

DRAINING TRACTS

The cause of draining tracts should be determined systematically using ultrasonography before a contrast radiographic examination is performed. Usually the source of drainage can be confirmed by ultrasonography if a thorough ultrasonographic examination is performed, eliminating the need to perform a contrast study. The injection of contrast material into the tract also results in the injection of air. This air may limit or prevent evaluation of foreign bodies within the tract because air is a nearly perfect reflector of ultrasound waves. The air that is injected with the contrast material may mix with the fluid within the tract, surround the foreign body, and obscure it from view.

A draining tract should be scanned systematically, keeping in mind that more than one factor may cause drainage. The clinician should start at the skin surface and follow the tract,, which usually appears as hypoechoic tissue that is oval to round in transverse section and somewhat tubular in longitudinal section. The draining tract usually is easiest to follow in transverse section, unless the

tract is short and straight.¹ The draining tract should be kept in the center of the ultrasound screen as it is followed into the deeper tissues. The tract may be single, or multiple tracts may be present. Often the tract is tortuous, and each branch of the tract should be followed to its source.¹ The source of the drainage at the end of the tract or tracts should be identified. Chronic draining tracts can originate from an area of osteitis or osteomyelitis; a sequestrum, foreign body, or necrotic tissue acting as a foreign body; an abscess; or a synovial structure.^{1,11} Once the source or sources of the drainage have been identified, appropriate decisions can be made regarding medical or surgical management.

FOREIGN BODIES

Foreign bodies vary in ultrasonographic appearance.¹⁰⁻¹⁹ The most commonly detected foreign bodies include suture material, wood, plant material, lead, and glass. Sequestered pieces of bone, hoof that becomes embedded in the soft tissues, and necrotic tissue also can create a foreign body reaction. Suture material usually is linear or tubular, is hyperechogenic, and casts an acoustic shadow. Wood usually appears as a linear hyperechogenic structure casting a strong acoustic shadow from its near surface.^{10,11,19} Plant material tends to appear as small echogenic material that casts either a weak acoustic shadow or no acoustic shadow. Embedded hoof appears as a hypoechoic to echogenic structure that often casts no acoustic shadow, or only a weak acoustic shadow is visible. The tubular composition of the hoof wall can sometimes be appreciated during the examination.

The ultrasonographic examination can be used to substantially shorten surgical time by accurately identifying the foreign body locations and identifying the relevant adjacent structures.^{10-18,20-22} The surgical approach can be made directly over the foreign body. The foreign bodies should be measured ultrasonographically in two mutually perpendicular planes preoperatively and then compared with the foreign bodies removed at surgery, helping the surgeon to confirm that all foreign material has been removed. Intraoperative localization of the foreign body also can be performed, if localization of the foreign body proves difficult at surgery, aiding the surgeon in its rapid removal.^{10,11,14,15,21}

BONE

A bone surface appears as a smooth, uniform-thickness hyperechoic line that casts an acoustic shadow from its near surface.^{1,4,11,12,18} Normal bony protuberances appear as bony shelves that are continuous with the parent portion of the bone. The continuity of an irregular bony surface echo can be followed ultrasonographically in at least one plane, differentiating this irregularity from a fracture. Vascular channels create breaks in the normal bony surface echo at the site of vessel penetration.

Fractures

Ultrasonography is useful in the diagnosis of fractures in areas that cannot be assessed radiologically, such as the withers, scapula, humerus, ribs, pelvis, femur, and tibia, and in finding fractures that are suspected but have not

Figure 18-2 • Transverse (*left*) and longitudinal (*right*) ultrasonographic images of a healing deltoideus tuberosity fracture. The original fracture (*large arrows*) was comminuted and displaced, with two of the cracks clearly visible in the bone in two mutually perpendicular planes. There is bony irregularity associated with early bridging of the fracture fragments with the underlying bone and echogenic tissue surrounding the fragments associated with fibrous tissue at the fracture site.

been detected with routine radiography.^{11,21,23-29} The ultrasonographic diagnosis of fractures depends on imaging the fracture line or fracture fragment in two mutually perpendicular planes.¹ A nondisplaced fracture is seen as a break in the normal hyperechogenic bone surface. Detection of a hyperechogenic bony structure distracted from the underlying parent bone in two mutually perpendicular planes is consistent with a displaced fracture fragment (*Figure 18-2*). In an acute fracture, anechogenic fluid with hypoechogenic to echogenic loculations in the surrounding soft tissues is present. Echogenic masses of all shapes (frequently oval) within the loculated fluid are consistent with clot. These masses usually cast an acoustic shadow from the far surface as they become more organized. Disruption of the surrounding musculature frequently is seen if a fracture is displaced.

Osteitis and Osteomyelitis

The detection of an extraarticular fluid layer immediately adjacent to bone and without an intervening soft tissue layer is diagnostic of osteitis or osteomyelitis, unless the area has sustained recent trauma^{1,18} (*Figure 18-3*). This ultrasonographic sign can be detected in horses with acute osteitis or osteomyelitis and precedes the detection of radiological changes by 10 to 14 days. Soft tissue swelling often is present in the tissues adjacent to the osteitis or osteomyelitis. In horses with early osteitis and osteomyelitis the bony surface echo immediately adjacent to the fluid layer usually has a normal ultrasonographic appearance. With increasing chronicity, irregularities are detected in the bony surface echoes that are also detectable radiologically. Thinning of the bony surface echo with scooped-out areas in the underlying bone is consistent with lysis. Irregular hyperechogenic bony spicules correspond to areas of bony proliferative change. Irregular bone has been imaged in lame horses with osteitis of the tuber calcanei.^{30,31} Osteitis occurs at the insertion of the gastrocnemius tendon in horses with a concurrent infectious or noninfectious calcaneal bursitis and can occur in horses

Figure 18-3 • Transverse (*left*) and longitudinal (*right*) ultrasonographic images of the distal metacarpal region of a horse with an acute onset of swelling, fever, and lameness associated with osteitis of the fourth metacarpal bone (McIV) and third metacarpal bone (McIII). A hypoechogenic fluid-filled tract in the subcutaneous tissues extends down to the McIV and McIII in the distal metacarpal region. A small hypoechogenic fluid layer overlies the McIV and the McIII and is indicative of osteitis (*arrows*) communicating with the tract extending out to the skin surface. There is a small fragment imaged distracted away from the underlying bone in the longitudinal view (*small arrow*). The echo from the McIV and the McIII is slightly thinner than normal, consistent with lysis associated with the infection of the bone.

with infectious tarsal tenosynovitis.^{30,31} Sequestra are imaged as hyperechogenic fragments that cast an acoustic shadow, are surrounded by anechogenic to hypoechogenic fluid, and are distracted from the parent bone.^{1,11,18} A linear wooden foreign body can mimic the ultrasonographic appearance of a sequestrum.

Ultrasonography is useful for the diagnosis of osteitis or osteomyelitis in horses with fractures where the radiological signs of fracture healing can be difficult to distinguish from those of infection.^{1,11,18} Bony lysis is a component of both fracture healing and infection. Immediately after trauma, or in the immediate postoperative period, fluid is detected adjacent to the bone for several days or longer until the local hemorrhage associated with the original injury or surgical trauma has resolved. A soft tissue layer should then cover the bone in all extraarticular locations.

The detection of a fluid layer directly overlying the bone in horses with suspected osteitis or osteomyelitis should prompt ultrasound-guided aspiration of the fluid, with or without biopsy of the area, and submission of the fluid or tissue obtained for culture and susceptibility testing and histopathological examination (tissue). If surgical curettage of the affected area is chosen, this can be performed at the time of surgery. Horses that receive long-term antimicrobial drugs for osteitis or osteomyelitis should be reevaluated ultrasonographically before the treatment is discontinued. A soft tissue layer should be present over the affected bone without any intervening fluid.¹ If treatment is discontinued while a fluid layer remains overlying the bone, recurrence of the osteitis or osteomyelitis is likely.

Bone Abscess

A bone abscess may be imaged ultrasonographically as a hypoechogenic, scooped-out area in the cortical and

medullary regions of the bones¹ and usually is seen in foals, often associated with *Rhodococcus equi* infections. Large adjacent subcutaneous abscesses may communicate with the bone abscess. A dynamic ultrasonographic examination displacing the fluid within the subcutaneous abscess may help to identify the defect in the underlying cortical bone.

Implants

The cause of a worsening lameness in horses with implants may be difficult to determine from the physical examination and radiological findings. Ultrasonographic examination can provide valuable information about the implant, bone, and surrounding soft tissue structures. In horses with surgical implants the detection of a fluid layer immediately adjacent to the implant, without an intervening soft tissue layer, is diagnostic of infection (Figure 18-4).¹ Infection of the implant, infection of the adjacent synovial structures, or problems associated with the implant itself often can be differentiated ultrasonographically. In horses in which fetlock or pastern arthrodesis was performed, worsening of lameness may be caused by infectious tenosynovitis of the digital flexor tendon sheath, which can be diagnosed ultrasonographically as hypoechogenic effusion within the sheath. Problems with screw placement can be identified as a probable cause of lameness, such as when a screw is inadvertently located within the deep digital flexor tendon, causing fiber disruption and tendinitis. The various implant materials (plate, screw, wire, or

Figure 18-4 • Transverse (left) and longitudinal (right) ultrasonographic images of the left femur from a foal with a plate and screw repair of a fractured femur with an infected implant. Notice the large hypoechoic fluid layer (vertical arrows) against the hyperechoic echo from the metal plate. This image was obtained 2 months postsurgery, when all of the hemorrhage associated with the fracture and its repair should have been resolved.

antimicrobial-impregnated polymethylmethacrylate bead) can be differentiated ultrasonographically by characteristic appearances. Thus the most likely cause of the horse's deterioration can be identified, and treatment can be targeted appropriately.

Chapter 19

Nuclear Medicine

Mike W. Ross and Vivian S. Stacy

GENERAL CONSIDERATIONS

Nuclear medicine is a relatively recent advance in diagnostic imaging of the horse, pioneered by Ueltschi¹ in Europe and Twardock and Devous^{2,3} in the United States. Seeherman and colleagues⁴ and Lamb and Koblik⁵ further demonstrated the value of bone scintigraphy in the evaluation of sports horses. For detailed description of procedures and interpretation of scintigraphic images, the reader is referred to *Equine Scintigraphy*.⁶

Bone scintigraphy is a way to reach within the horse and extract clinically useful and relevant information and helps to answer many lameness questions that we previously could not answer. Scintigraphy is used to assess the current status of known radiological abnormalities, pursue diagnosis in horses with negative or equivocal radiographs, screen horses with obscure forelimb or hindlimb lameness, and evaluate horses with poor performance. Scintigraphy can be useful to corroborate functional information gained with other advanced imaging modalities such as magnetic

resonance imaging (MRI). However, a gamma camera is not an answer machine, and it is critically important to correlate scintigraphic findings with clinical lameness examination findings. Scintigraphy can play an important role as a screening tool but should never replace diagnostic analgesia. In fractious or highly strung horses with hindlimb lameness, scintigraphic examination may be used to provide a diagnosis, but clinical relevance still should be confirmed.

Nuclear medicine involves the *in vivo* or *in vitro* use of radioisotopes in the diagnosis and management of clinical disease. Several terms are used synonymously with *nuclear medicine*, including *nuclear scintigraphy*, *bone scintigraphy*, and *gamma scintigraphy*, and although these terms differ slightly, for horses most clinicians refer to *bone scintigraphy*, the technique most commonly performed. Bone scintigraphy is highly sensitive compared with radiography. It can detect as little as 10^{-13} g of radiopharmaceutical in bone, whereas changes measured in grams must occur before a lesion can be detected using radiography.³ Important factors that decrease sensitivity include time from radiopharmaceutical administration to image acquisition, body part-to-camera distance, shielding, motion, time from injury to image acquisition, ambient temperature and peripheral perfusion, and amount of background radiation. For example, the combination of negative factors including high background radiation, motion, endogenous shielding, and distance reduce the sensitivity of pelvic and other axial skeletal scintigraphic imaging and that of upper limb imaging in both the forelimb and hindlimb. High

sensitivity (94.4%) in horses with extremity fractures was found, but a lack of sensitivity in pelvic imaging was suggested.⁷ Specificity is low compared with other modalities because disparate diseases can similarly alter blood flow and binding sites in bone. Direct trauma (osteitis) and fracture; stress-related bone injury, including fracture and osteoarthritis (OA); infection (infectious osteitis and less frequently osteomyelitis); osteochondrosis; enostosis-like lesions; and neoplasia are in theory difficult to differentiate scintigraphically. Accuracy can be improved by acquiring several images from different perspectives, minimizing factors affecting sensitivity, and knowing the history. For example, a focal area of increased radiopharmaceutical uptake (IRU) in the caudolateral tibial cortex of a 2-year-old Thoroughbred (TB) filly would undoubtedly represent stress-related bone injury rather than a rare bone tumor.

Radiographs depict activity in bone that has already occurred in the past several days to years. Scintigraphy is a *functional* evaluation of bone at the time of imaging. Scintigraphic evidence of bone activity means active bone formation, bone *modeling*, is occurring that might take weeks to be visible radiologically. Therefore a major advantage of scintigraphy is *early detection* of bone injury. Scintigraphy will unlikely accurately reflect changes in bone that occurred longer than 3 to 4 months before imaging. Horses given substantial rest before examination are not good candidates unless the examination is a follow-up to assess healing.

SCINTIGRAPHY AND OTHER IMAGING MODALITIES: WHERE DO THEY FIT?

Recent advances in imaging such as digital radiography (Chapter 15), computed tomography (CT; Chapter 20) and MRI (Chapter 21) have led to questions about the role of scintigraphy in lameness diagnosis. We are often asked questions such as, "Would you use scintigraphy or MRI for diagnosis?" and "Should I put MRI or scintigraphy into my practice?" We would not choose to be without the ability to use scintigraphy in lameness diagnosis. We believe that the combined and concurrent use of scintigraphy and MRI yields the most useful and relevant information and that seldom, given strict case selection, is information redundant. At the origin of the suspensory ligament in the proximal aspect of the third metacarpal and metatarsal bones, a complex area from which pain commonly originates, a combination of imaging modalities is most useful to characterize soft tissue and bony injury. Likewise, lameness abolished with palmar digital analgesia is complex, and the concurrent use of advanced imaging modalities provides complementary information. Nuclear scintigraphy has proved useful in the investigation of foot pain, specifically from the podotrochlear apparatus, and has helped determine clinical significance of lesions discernible with MRI, because a positive correlation between scintigraphy and MRI grades in lesions of the navicular bone was found.^{8,9} We believe that both scintigraphy and MRI are critical for addressing complex lameness questions.

RADIOISOTOPES AND RADIOPHARMACEUTICALS

A radioisotope emits radiation (particles) that is captured using a scintillation camera. Radioisotopes such as

indium-111 (¹¹¹In) are used occasionally, but the most common and useful radioisotope is technetium-99m (^{99m}Tc). ^{99m}Tc, a short-lived (metastable) radioisotope with a half-life of 6 hours, is ideal for radiation safety and horse retention. ^{99m}Tc is excreted almost entirely through the kidneys, so containing and monitoring urine is extremely important. ^{99m}Tc is produced when molybdenum-99 (⁹⁹Mo) decays to ^{99m}Tc. The metastable (^{99m}Tc) radioisotope gives off a gamma ray (140 keV) that is used for imaging. Commercially, ⁹⁹Mo and ^{99m}Tc generators can be purchased for use in large hospitals, but an alternative, cost-effective method is the daily purchase of individual doses, a practice that obviates the need to house generators. Directly from the generator, ^{99m}Tc is in the ionic form of sodium ^{99m}Tc pertechnetate (Na^{99m}TcO₄) that can be injected or mixed with a bone-seeking agent or pharmaceutical. Radiation is measured in curies (Ci) or millicuries (mCi); becquerels (Bq), megabecquerels (MBq), and gigabecquerels (GBq) are also used. One millicurie is equal to 37 MBq. The recommended dose of ^{99m}Tc is 0.4 to 0.5 mCi (14.8 to 18.5 MBq)/kg, totaling 150 to 200 mCi (5.5 to 7.4 GBq) per horse. Low doses reduce radiation exposure but prolong acquisition time or may result in inadequate image quality if insufficient counts are obtained. High doses may actually reduce overall radiation exposure by limiting exposure time.

Na^{99m}TcO₄ can be injected intravenously directly, but only flow and pool phase studies can be performed. For most equine studies, Na^{99m}TcO₄ is mixed with a pharmaceutical. For bone, ^{99m}Tc is bound to methylene diphosphonate (MDP), or hydroxymethane or hydroxymethylene diphosphonate (HDP, HMDP). MDP is slightly less expensive and is the most common pharmaceutical used worldwide, but we prefer HDP because the kidneys clear it slightly faster, allowing early acquisition of delayed phase images. Henceforth MDP and HDP are used interchangeably.

The exact mechanism of binding of ^{99m}Tc-MDP to bone remains unclear. ^{99m}Tc-MDP is thought to bind to exposed sites on the inorganic hydroxyapatite crystal. Binding sites are exposed under normal and pathological conditions in areas of actively remodeling bone or in soft tissues undergoing mineralization.^{10,11} ^{99m}Tc-MDP uptake occurs by the processes of chemical adsorption onto, and by direct integration into, the crystalline structure.¹² Other possible mechanisms to account for increased uptake include incorporation into the organic matrix or local hypervascularity.¹¹ In rat models, ^{99m}Tc was found to be incorporated into the organic matrix rather than the inorganic portion of newly formed bone.^{13,14} Radiopharmaceutical may dissociate with incorporation of ^{99m}Tc and MDP individually into the organic and inorganic phases, respectively.¹⁵ ^{99m}Tc-MDP adsorption might depend on pH and the presence of phosphates, calcium compounds, and other cations.¹⁶

Accumulation of ^{99m}Tc-MDP is not simply the result of changes in local blood flow, although blood flow is likely increased in sites of actively remodeling bone. Although increased blood flow does not significantly affect a bone scan,¹⁰ *adequate* blood flow is necessary to deliver radiopharmaceutical to available binding sites in bone. Poor correlation was found between perfusion index and radiopharmaceutical uptake (RU) in delayed images when evaluating people undergoing distraction osteogenesis.¹⁷ This study suggested that blood flow is not closely linked to

bone metabolism and that delayed images most accurately predicted osteogenesis.¹⁷ Rather than measuring blood flow, delayed images reflect changes in bone metabolism. When three-phase bone scintigraphy was used in people with osteonecrosis of the jaw secondary to bisphosphonate administration, delayed images were all positive, but increased perfusion (and increased blood pool) was found in 9 of 12 patients.¹⁸ A three-phase bone scan can detect increased perfusion and soft-tissue inflammation if present, but it is metabolic activity of bone that influences delayed phase images. Decreased blood flow, caused by infarction or ischemia, can greatly affect a bone scan but is an unusual clinical problem (see discussion of photopenia, page 226). However, decreased peripheral blood flow in old horses or those imaged in cold weather or on days with high diurnal temperature change can adversely affect image quality (see discussion of poor-quality bone uptake, page 222).

The most important aspects of ^{99m}Tc -MDP binding relate to timing of the scan and the stage of modeling (formation). In actively remodeling bone, osteoclastic activity predominates during bone resorption, whereas osteoblastic activity dominates during bone modeling. Modeling occurs independently or in conjunction with remodeling in cancellous and cortical bone. Histological and scintigraphic findings were evaluated in a rat tibial evacuation model, and ^{99m}Tc -MDP was found to bind to sites of active calcification, most prevalent 12 days after injury.¹⁹ ^{99m}Tc -labeled phosphonates were identified during bone formation, and ongoing resorption was not necessary for increased uptake to occur.¹² ^{99m}Tc -MDP accumulated in areas of calcification or in fixed bone fragments,^{12,20} and accumulation was mediated by osteoblastic activity.¹² The high sensitivity of bone scintigraphy is attributed to increased osteoblast activity that precedes morphological changes visible radiologically.²¹ Other mechanisms may exist, however, because positive bone scan results may be seen in people with diseases such as osteomalacia, in which high bone matrix turnover and failure of calcification occur.¹⁹

Site and stage of binding are important from a clinical perspective. Binding sites for ^{99m}Tc -MDP are created by osteoblast activity during bone modeling, and maximal IRU occurs 8 or 12 days after bone injury.^{19,22} An acute fracture caused by direct trauma may not be scintigraphically evident for several days. Acute, traumatic injury differs from stress-related bone injury, because the latter, particularly common in racehorses, results from a continuum of bone changes that might lead to stress or catastrophic fractures and OA. Microfracture, periosteal callus, and subchondral bone damage precede the development of stress or complete fracture in the dorsal cortex and distal articular surface of the third metacarpal bone (McIII), the third metatarsal bone (MtIII), the humerus, the tibia, and the pelvis.²³⁻²⁵ In horses with acute lameness from stress-related bone injury, bone scan findings usually are immediately positive because bone modeling is ongoing. In horses with stress-related bone injury a bone scan result is likely to be positive long before catastrophic fracture occurs, an important advantage of scintigraphy compared with radiography. In horses with traumatic injury, such as an acute pelvic or other upper limb fracture, a false-negative scan result may occur from lack of modeling. Other factors resulting in false-negative results include

distance, shielding, high background activity, and motion. For example, a horse developed acute hindlimb lameness during hospitalization, and, suspecting a pelvic fracture involving the acetabulum, clinicians performed scintigraphic examination on day 2, but the scan result was negative. On day 9 faint IRU appeared, consistent with fracture.

In horses with stress-related bone injury and traumatic injury a considerable decrease in RU occurs within 6 to 8 weeks after injury. Decreased intensity after fracture varies with the specific bone and fracture type. The ideal time to image, particularly in horses with pelvic or other axial skeletal trauma, is 10 days to 8 weeks after injury, although positive bone scan findings are often obtained in horses with distal extremity fractures 72 to 96 hours after known trauma.

Given the short half-life of ^{99m}Tc , it is the most widely used and versatile radioisotope when imaging a lame horse and for most nuclear medicine procedures in horses and people. The same radioisotope injected intravenously, ^{99m}Tc , can be combined with different drugs (pharmaceuticals) to target different tissues. For example, for lung perfusion images to be obtained, macroaggregated albumen is labeled with ^{99m}Tc ; for brain imaging, glucoheptanate is labeled with ^{99m}Tc . Standard ^{99m}Tc -HDP is used for sinus, dental, and temporomandibular joint imaging and can be used to evaluate peripheral vasculature in first-pass studies after intravenous injection or by injection directly into distended peripheral veins for evaluation of venous return. To obtain high levels of radiopharmaceutical in the distal extremities for specific imaging or to perform experimental studies, $\text{Na}^{99m}\text{TcO}_4$ can be administered using intraosseous or intravenous regional limb perfusion techniques.²⁶ Our preliminary results with this technique show uneven distribution within distal limb tissues and persistence of radioisotope in large, distended veins. Peripheral lymphatic fluid dynamics can be studied using ^{99m}Tc -sulfur colloid injected directly into distended lymphatics or subcutaneous tissues.²⁷ Soft tissues are most commonly imaged using three-phase bone scintigraphy with ^{99m}Tc -HDP (MDP), but recently, radiolabeled biotin was found to be safe and useful to detect soft tissue inflammation without concurrent uptake of the radiopharmaceutical in bone.²⁸ We have limited experience using radiolabeled white cells to image osteitis, osteomyelitis, and cellulitis in horses, and although the technique is occasionally useful, our results do not appear as promising as those previously reported.²⁹ Briefly, white blood cells harvested from affected horses or foals are labeled with ^{99m}Tc and hexamethylpropyleneamine oxime (^{99m}Tc -HMPAO) and then reinjected to allow accumulation at sites of infection. Infection imaging is an important topic in human medicine, and advances in equine imaging using novel agents such as antibodies or antimicrobial agents may hold promise.³⁰

IMAGING EQUIPMENT

Scintigraphy can be performed in two ways, but the most common and useful method is acquisition of two-dimensional images with a gamma camera. Alternatively, a handheld probe is used to acquire count density computer-generated charts, or graphs are created to determine IRU. Known as *probe point counting*, this form of

Figure 19-1 • The nuclear medicine facility at New Bolton Center, University of Pennsylvania, has large field of view and small field of view cameras. A custom-made central column overhead gantry holds the rectangular large field of view camera, which can be lowered below floor level to image the distal extremities.

scintigraphic examination was first introduced in 1984.^{31,32} Some probes are like miniature gamma cameras built with a single photomultiplier tube. Crystal probe detectors are more expensive than the photomultiplier detectors, but they are small and easily used on the body surface, or per rectum in horses with suspected pelvic fracture.³² Probe point counting is done with a substantially lower radioisotope dose, minimizing cost and radiation exposure. Probe point equipment is inexpensive. Because the probe is placed directly on the skin surface, body part-to-probe distance is minimal. A gamma camera is often difficult to get close to the body surface, a problem that can prolong acquisition time and decrease image quality. A good correlation appears between results of probe point counting and gamma camera imaging in acute injuries in young horses, but in older horses the technique has limited sensitivity. However, quantitative information is available only as a histogram, and an actual image allowing qualitative assessment is not obtained.

Gamma camera images are obtained in analog or digital form, and permanent hard copies of a two-dimensional scintigraphic image are generated. In people, one or several gamma cameras operating simultaneously can be used to generate a cross-sectional image similar to a CT or MRI scan. This is known as *single photon emission CT* (SPECT) and *photon emission tomography* (PET). Although SPECT and PET imaging are theoretically possible in anesthetized horses, we are not aware that the techniques have been performed.

A reconditioned gamma camera is perfectly satisfactory, less expensive than new equipment, and durable, often being useful for at least 15 to 20 years or more, with proper maintenance. Gamma cameras are either large field of view (LFOV) or small field of view (SFOV), based simply on the size (Figures 19-1 to 19-3). LFOV cameras can be rectangular or circular in shape, but crystals for rectangular cameras are more costly. In adapting equipment for use in horses, an important consideration is how to move the camera safely and easily to the horse and vice versa. Most standard gantry (support structure of the gamma camera) designs are unsuitable for equine imaging, because good-quality images can be obtained only by having the body

Figure 19-2 • The small field of view camera in the floor allows easy acquisition of solar images of the foot. After a wooden cover is applied, the horse stands over the small field of view camera for the solar image. A lead-lined wrap placed around the coronary band region shields the foot and camera from radiation emanating from the more proximal aspects of the affected limb.

Figure 19-3 • Construction of a recess or pit into which the large field of view camera can be lowered allows imaging of the distal extremities with minimal movement of the horse. The lateral aspect of the hoof touches the face of the camera (clear polycarbonate protects the collimator). This position minimizes distance and improves resolution, improves image quality, and decreases acquisition time. A curved, lead-lined shield protects the camera and left forelimb from radiation emitted by the right forelimb.

part close to the camera. Resolution is inversely proportional to the distance between the body part and camera. To quickly obtain dorsal and lateral, and lateral and plantar, images of the forelimbs and hindlimbs, respectively, the camera must be able to be lowered below floor level (see Figure 19-3). Alternatively, the horse must be positioned on an elevated platform. Limbs can be held manually near the camera, but this practice increases radiation exposure to personnel and should be avoided whenever possible. Suitable gantries are commercially available or can be custom made. A lead collimator is also required.

IMAGE ACQUISITION

For flow and pool phase images, horses are sedated and positioned in front of the camera, and ^{99m}Tc-HDP (or MDP) is injected intravenously. Delayed phase images are then

Figure 19-4 • Delayed phase scintigraphic images of an 8-year-old Thoroughbred with neurological signs consistent with compression of the cervical spinal cord. **A**, Corrected (*left*) and uncorrected (*right*) right lateral images (cranial is to the right) showing marked improvement in image quality using motion correction techniques. Note there is normal radiopharmaceutical uptake in the intervertebral joint between the third (Cr3) and fourth cervical vertebrae. **B**, Laterolateral digital radiographic image (cranial is to the right) of the cervical spine showing marked osteoarthritis in this intervertebral joint (*arrows*). Based on lack of cervical stiffness or pain and normal scintigraphic activity, this radiological change was considered old and inactive. **C**, Right lateral scintigraphic image of the caudal cervical spine showing narrowing (*arrow*) of the vertebral canal between the fifth and sixth cervical vertebrae, a finding validated using myelography. Useful anatomical information can be obtained from scintigraphic images.

obtained 2 to 4 hours later. Scintigraphic images are produced when the horse, now the radiation source, emits gamma rays from normal and abnormal bone. The gamma rays must pass through overlying tissues and traverse the distance between the body part and the camera. An area of IRU emits more gamma rays than does adjacent normal bone and contributes more counts to the scan. Sites farther from the camera, those being shielded by overlying soft tissue or adjacent bone, or those in areas of high background activity may not be visible, because they may not contribute enough gamma rays. Gamma rays strike a sodium iodide crystal, and scintillations produced are detected and amplified by photomultiplier tubes that subsequently transmit information through electronic circuits. The image is displayed on an oscilloscope or sent directly to a film processor, called *analog imaging*. Alternatively, information is transmitted to a computer, stored digitally, manipulated, and subsequently sent to a film processor or printer.

An important recent advancement is the ready availability of user-friendly computer programs to acquire, analyze, store, and process images. Systems based on Apple, Windows, and Unix are currently available and are straightforward. Motion correction software is the latest, exciting advance; it improves upper limb and axial skeleton image quality by negating the effects of motion and allowing higher count numbers than with conventional software

(*Figure 19-4*). Modern software also allows postprocessing of images—for example, masking out the bladder, which might otherwise steal counts.

Images are obtained in either static or dynamic mode. Static images, most commonly obtained, are acquired using a predetermined number of counts per image. For example, because motion and soft tissue covering are limited in the distal limbs, good-quality images can be obtained using 100,000 to 150,000 counts per image. In general, increasing counts per image improves image quality, but for more counts to be acquired, time and motion become factors. Motion correction can add flexibility.

A fundamental principle of image interpretation is comparing images of one limb with those of the contralateral limb, but the clinician should keep in mind that both limbs, and for that matter all limbs, can be abnormal. To compare limbs accurately using this technique, body part-to-camera distance and camera position relative to the limb must be standardized between limbs. Time to acquire each image ranges from 30 to 90 seconds depending on radioisotope dose, type and age of horse, and ambient temperature. Time rather than count number can be standardized, assuming that limb perfusion is adequate and symmetrical. For example, lateral images of both metacarpal regions are obtained for 90 seconds and compared.

The number of images to obtain is based on the body part being examined, but usually at least two images are

Figure 19-5 • Delayed phase scintigraphic images of a horse with a fracture of the medial aspect of the right forelimb (RF) distal phalanx. The lateral (LAT) image of the right forelimb does not show the area of increased radiopharmaceutical uptake, and little difference is noted between both front feet. The dorsal and solar images, however, clearly show increased radiopharmaceutical uptake. It is extremely important to obtain more than one scintigraphic image. LF, Left forelimb.

required. In some areas this may not be possible, but the clinician should be aware that false-negative results can occur. A dorsal scintigraphic image gives detailed information about only the dorsal aspect of the limb, and abnormal palmar regions might be missed. The image and information are not the same as depicted in a dorsopalmar radiographic image. Similarly, areas of IRU on the medial side of the limb might not be visible on a lateral image. Areas more distant from the camera contribute substantially less radiation than those closer because of the inverse square law. Bone interposed between a medial lesion and the camera can effectively shield the site. A lateral image of a right forelimb failed to reveal a fracture of the medial aspect of the distal phalanx (Figure 19-5). Radiographic examination and dorsal and solar scintigraphic images, however, revealed an incomplete fracture that we completely missed in the lateral scintigraphic image. Additional images may be necessary for accurate diagnosis.

We prefer to localize lameness, because this allows for detailed examination of a specific area. For instance, routine screening images of the front digit include lateral and dorsal delayed images, but in horses in which lameness is abolished using palmar digital analgesia, pool phase images and lateral, dorsal, solar, and occasionally medial, palmar, and flexed delayed images are obtained. Diagnostic accuracy can be improved by acquiring many different images, and pinpointing a lesion using scintigraphy can allow a focused radiographic, ultrasonographic, CT, or MRI study to be performed. Combined imaging can yield additional useful information.^{8,9} When augmenting the routine dorsal and plantar images of the metatarsophalangeal joint with flexed lateral and sometimes flexed dorsal and medial images, instead of saying, “There is IRU in the fetlock joint,” the diagnostician can say, “There is focal IRU involving the distal, plantarolateral aspect of the MtIII,” a much more accurate description (Figure 19-6).

Dynamic acquisition can be used before motion correction in delayed images or to evaluate blood flow. One- or 2-second per frame images are generated sequentially and can be evaluated individually or combined into a single composite image, with or without motion correction. First-pass angiography can be used to assess blood flow in the aorta, iliac, and femoral arteries³³ in horses with suspected thromboembolism (Figure 19-7) or to assess blood flow in the distal limb.

Image Quality

Factors that contribute to poor image quality are related to the horse and to processing. Analog (old way) and digital (new way) processing provide good-quality images provided the equipment is working properly. Regular quality control is absolutely essential to maximize image quality and avoid artifacts. A cracked or poor-quality collimator, sodium iodide crystal damage, malfunction or incorrect tuning of photomultiplier tubes, electric circuit malfunction, age, and poor general condition of refurbished equipment can cause artifacts or gradual deterioration in quality or can completely shut down the process. The dose of radioactivity administered, the number of counts acquired, image distance (distance from body part to camera surface), motion, and background radiation are most critical. As many gamma rays as possible from the affected bone must reach the crystal without motion for image quality to be maximized.

Number of Counts

Image acquisition, the principles of using count numbers as opposed to time, and the importance of standardizing images between limbs were discussed earlier. One limb may overall be more active than the contralateral limb and count faster in individual images or contribute more counts when combined in images of both limbs. Horses with

Figure 19-6 • Lateral (left), dorsal (second from left), flexed lateral (second from right), and flexed dorsal delayed phase scintigraphic images of the right forelimb (RF) of a 2-year-old trotter with subchondral bone injury. The flexed lateral and dorsal images best show the focal area of increased radiopharmaceutical uptake involving the distal, medial aspect of the third metacarpal bone. Although increased radiopharmaceutical uptake appears in other images, the flexed dorsal image allows differentiation of increased radiopharmaceutical uptake involving the third metacarpal bone and the proximal phalanx.

Figure 19-7 • Composite scintigraphic image generated after dynamic acquisition of 32 sequential images (2 seconds per frame) with the gamma camera positioned over the terminal aorta and branches. Imaging started 20 seconds after administration of ^{99m}Tc -hydroxymethane diphosphonate in the external jugular vein (cranial to the left, right is to the top). **A**, In a normal horse the external iliac arteries show a V-shaped divergence and a linear caudal course of the internal iliac arteries is seen. **B**, In this horse with aortoiliac thromboembolism, the direction and contour of the external iliac arteries is disrupted and the internal iliac vessels lack recognition.

unilateral lesions in the digit, such as those with distal phalanx fractures and soft tissue injuries, appear to have compensatory IRU normally in the rest of the limb. Our experience suggests that horses with distally located lesions in the affected limb often have more prominent normal uptake in delayed images in that entire limb, but others suggest that the nonlame contralateral limb may be more active because of increase in weight bearing.³⁴ An area of intense IRU present with a condylar fracture or stress-related bone injury may overwhelm the contribution of normal bone, making it difficult to see, a phenomenon called *count stealing*.

Distance

Having the affected body part too far from the camera is likely the most important factor contributing to false-negative bone scan findings. The ability of the camera and imaging system to resolve lesions is inversely proportional to distance. OA and subchondral bone cysts involving the

medial femorotibial joint can be completely missed unless a caudal image is obtained, simply because the lesions cannot contribute enough counts to the scan to be visible. Distance is too great. Pelvic images are dramatically and negatively affected by distance. Even if the camera is resting on the skin of the rump, some bones are still many centimeters away.

Shielding

Shielding is important in radiation safety, but it can be a negative factor in image quality and interpretation. Shielding helps or harms image quality and interpretation. High background radiation reduces image quality, because unwanted tissues steal counts. Pool phase images of the thoracolumbar spine and pelvis are rarely informative because within 1 to 2 minutes after injection, radiopharmaceutical in the kidneys and urinary bladder creates such high background levels of radiation that soft tissue lesions are missed. Delayed pelvic images are similarly affected by urine retention in the bladder. Bladder uptake causes poor image quality by creating high background levels of radiation and by superimposition on the sacrum in dorsal images. To avoid this problem, the bladder should be catheterized or a diuretic should be given. Lead shields can be placed on the skin between the bladder and camera, and count subtraction techniques can be used to take away bladder counts, but maximizing image quality by initially limiting radioactive urine is best.

Internal shielding can be a problem for interpretation. Gamma rays originating from a lesion distant to the camera must traverse bone, interposed soft tissue, and air before striking the camera. In a lateral image of the stifle, gamma rays originating from subchondral bone of the distal medial aspect of the femur must traverse the thick lateral condyle, dense ligaments, and other soft tissues, all while competing with gamma rays from other sources. Intuitively it would seem that counts would be additive, meaning a lesion medially would add to the counts normally originating from the lateral aspect, clearly showing the abnormal area. Acquiring images with sufficient counts reduces the risk of false-negative scan results. *Bone stacking*, when bones are superimposed, may explain normal areas of greater RU

visible in a lateral image of the coxofemoral joint. However, often bone interposed between a lesion and the camera seems to provide unwanted shielding. Overlying skeletal muscle may also provide unwanted shielding in pelvic images. Asymmetrical muscling caused by gluteal atrophy can explain mild differences in RU between left and right sides of the pelvis.

Motion

Two sources generate excess motion: movement of the camera or the horse. Swaying of cameras hung by hoists or chains and movement induced by the horse leaning on the camera result in poor image quality. In the distal limbs, horse movement is usually not a factor and acquisition times are short. Horses sway minimally when the distal limbs are scanned, but sway excursion is large in the upper limbs because of a longer pendulum effect from the anchor point (feet). Sedation may accentuate the effect. Motion detracts greatly from upper limb and axial skeleton image quality. We use detomidine (0.008 to 0.01 mg/kg) and butorphanol (0.006 to 0.075 mg/kg), a combination that allows optimal acquisition while minimizing motion. Manual support on each side and resting the horse's head on a stationary object partially negate the tendency of the horse to sway and drift. Motion correction software is useful in improving image quality but cannot compensate for all movement.

Background Radiation

High background radiation contributing to count stealing and handling bladder interference have been discussed. Shielding the limb or body being imaged with custom-made lead-lined barricades (see Figure 19-3) or placing drapes on the horse or around the body part (see Figure 19-2) helps isolate the region being examined. Old horses, large-breed horses, and fat horses and those with extensive swelling or fibrosis in the distal limbs often have high background activity in soft tissues, which inevitably results in poor-quality delayed images.

Poor-Quality Bone Uptake

Image quality in large breed horses such as TB crosses, Warmbloods, and draft horses or in old horses may be poor despite following accepted protocol. Average image quality in large-breed horses may be worse than in young racehorses for many reasons, but age and type of exercise might explain some differences. Large-breed performance horses tend to be older than the racehorse population, lack normal physeal activity, and often have dense soft tissues and large bones in the distal limbs. Exercise type and level in this type of horse are much different from those in racehorses. A relative lack of stress-related bone injury in subchondral and cortical bone limits the number and type of scintigraphic changes seen.

Image quality in all types of horses may be compromised in areas with cold weather or great diurnal temperature differences, especially in fall, winter, and early spring.³⁵⁻³⁷ Reduced radiopharmaceutical uptake generally occurs distal to the antebrachium and crus, either bilaterally symmetrical or asymmetrical. Delayed phase images acquired above the carpus and tarsus have high background radiation but can be adequately interpreted. A compensatory area of intense IRU may occur in the distal aspect of the

Figure 19-8 • A, Delayed phase scintigraphic image of an aged Warmblood gelding shows reasonable quality bone uptake in the proximal aspect of the limb and diffuse moderate increased radiopharmaceutical uptake in the distal aspect of the tibia. **B,** This delayed phase image is consistent with a pool phase scan of the tarsus and distal extremity. This abnormal pattern of poor bone uptake commonly appears in horses imaged in cold weather or in large breed horses.

radius and tibia. Distally, from the carpus and tarsus to the sole of the foot, images resemble pool phase images even when acquired 3 hours after injection (Figure 19-8). Occasionally a different pattern appears, with compensatory focal intense IRU in the distal radius and tibia, relative photopenia of the carpal and tarsal bones, and reduced to normal or interspersed (spotty) uptake in the metacarpal or metatarsal regions and digit. This phenomenon is not related to renal clearance, radiopharmaceutical affinity, or dose of radioisotope but appears to be caused by poor peripheral perfusion.³⁷ Normal horses appear to be able to shunt blood away from the periphery, presumably a homeostatic mechanism involving high sympathetic tone during times of abrupt drop in ambient temperature. Other related factors that might increase sympathetic tone are dehydration, stress, and transportation of the horse shortly before injection of radiopharmaceutical. High sympathetic tone may reduce blood flow in the distal extremity, and the radioisotope may be unable to reach available binding sites in bone. Blood supply must be adequate to ensure distribution of radiopharmaceutical to sites of osteoblast activity. Persistence of radiopharmaceutical in soft tissues and vessels in the distal extremity and occasional photopenia of the carpal, tarsal, or other bones cannot be explained.

We prefer that all horses be hospitalized the night before examination to avoid the problem of poor-quality bone uptake and to maximize image quality. This may reduce stress and improve hydration status. Keeping the distal limbs warm with bandages and, when the temperature is cold, applying a body blanket to maintain core temperature may help. In a recent study, Dyson and colleagues³⁷ found that exercise, but not the use of bandages to create warming, before injection was most important in improving peripheral blood flow and maximizing image quality in all types of horses. Horses are lunged or trotted on a treadmill for 15 to 20 minutes before injection. When

we suspect poor-quality scans may result, we administer acetylpromazine (15 to 20 mg per adult horse) before injection, a practice we feel helps ensure good-quality delivery of radiopharmaceutical to peripheral tissues. In a recent study acetylpromazine caused vasodilatation, increased blood flow, and count density in flow phase images and caused earlier onset of the flow phase in normal horses but did not influence count density in delayed phase images.³⁸ However, effects of acetylpromazine in horses with poor peripheral perfusion and abnormal bone uptake of radiopharmaceutical are unknown. If poor-quality images result despite following these procedures, the procedures should be repeated the next day after exercise, if possible.

RADIATION SAFETY

Rules for radiation safety and licenses to obtain and house radioactive materials differ for each state and country. In Pennsylvania, as of March 2008, a license to use radioactive materials must be obtained from the state Department of Environmental Protection, whereas before, a license was obtained directly from the federal Nuclear Regulatory Commission (NRC). Pennsylvania rules for use of radioactive materials agree with and match (are said to be “in agreement” with) those issued by the NRC. Horses are quarantined for 24 hours after injection and can then leave with instructions to avoid unnecessary contact with them for an additional 36 hours. Radiation levels at the horse’s body surface range from 0.4 to 0.7 mR/hr at 24 hours after injection, well below the trigger level of 2.0 mR/hr established by the NRC. Horses are kept in defined stalls in which solid waste removal is used (stall drains are plugged; shavings or straw are used for bedding). Waste is kept for 60 hours, at which time radiation levels do not differ from background.

We practice the concept of ALARA (as low as reasonably achievable) and attempt to maximize distance from horse to handler and minimize total imaging time. Persons handling radioactive materials wear body and ring badges, and all those in contact with horses wear body badges. Total yearly radiation exposure for full-time technicians is approximately 500 mR/yr (450 horses scanned each year). Most radiation exposure occurs during image acquisition, throughout which time a handler is in close proximity to the horse being imaged (radiation exposure is inversely proportional to the square of the distance). Ninety percent of total exposure has been shown to occur during image acquisition; there was no difference in exposure between persons drawing up the radiopharmaceutical and those holding the horse during its administration, but the person holding the horse during image acquisition received twice the exposure as the person operating the equipment.³⁹ Lead aprons, although not commonly worn, have been shown to significantly reduce radiation exposure in people performing equine scintigraphy.⁴⁰ Daily monitoring of selected sites and weekly wipe tests are performed. Nuclear medicine techniques in horses can be done safely, within NRC or other supervisory guidelines, without undue contamination or exposure.

BONE SCAN PHASES

The bone scan is divided into three phases named for the tissues in which the majority of radiopharmaceutical

resides at that time. Flow phase (phase I, vascular phase) images are obtained for 1 to 3 minutes after injection, during which time radiopharmaceutical resides in blood vessels. First-pass studies of the heart and major central and peripheral vessels can be performed (see [Figure 19-7](#)). The flow phase appears to last longer in horses than in people, because radiopharmaceutical persists in distal limb veins often for greater than 10 to 15 minutes, a finding that can complicate interpretation and potentially decrease sensitivity of pool phase images. Pool phase (phase II, soft tissue phase) images are classically obtained 3 to 15 minutes after injection, during which time radiopharmaceutical resides in the extracellular fluid pool. Pool phase images are used to evaluate soft tissues such as tendons, ligaments, tendon sheaths, and bursae. A common misconception is that many distant soft tissues can be evaluated, but the short time interval dictates careful selection of sites for pool phase imaging. Delayed phase (phase III, bone phase) images are obtained 2 to 4 hours after injection, during which time radiopharmaceutical resides in bone and unbound drug has cleared the kidneys. Although information gained in flow or pool phase images is useful, delayed images are the mainstay of equine imaging. A three-phase bone scan involves acquisition of flow, pool, and delayed images, but most commonly only delayed images, or delayed and selected pool phase images, are obtained. An area of IRU visible in all three phases could indicate bone trauma, fracture, or infection, but in horses it generally indicates trauma or fracture. Pool phase and delayed phase images should be carefully evaluated to determine if areas of IRU are the same or different. In our experience, early pooling of radiopharmaceutical usually represents early bone uptake. Pool phase and delayed phase images can be superimposed, or region of interest (ROI) analysis can be used to determine size and position of IRU. In the proximal palmar metacarpal or plantar metatarsal regions, uptake of radiopharmaceutical can occur in only bone, only soft tissue, or both, and prognosis in horses with suspensory desmitis or bony injury can vary with tissue involved. Fractures are evident in delayed images, but sometimes they are visible as early as 20 to 30 seconds after injection or as progressive IRU in all phases. In horses with suspensory desmitis without bony involvement, pool phase images may indicate positive findings in horses with acute injuries but are often negative, whereas delayed phase images are often negative or equivocal. Scintigraphy is often castigated for its inability to detect proximal suspensory desmitis, but keep in mind that most horses have only soft tissue and not bone pain. In a recent study of proximal suspensory desmitis most horses had normal subjectively and objectively determined RU, and poor correlation between bone scan and radiological abnormalities was found.⁴¹ Abnormal ultrasonographic findings in conjunction with diagnostic analgesia remain hugely important in diagnosis of proximal suspensory desmitis. Differentiating soft tissue injury from that of bone is particularly important in the foot. Bruises, laminar tearing, and subsolar abscesses should cause positive results on pool phase images, but negative or equivocal delayed phase images. In horses with long-standing infection or inflammation, osteitis of the distal phalanx can cause IRU in delayed images, complicating differentiation of involvement of the two tissues. Conversely, early bone uptake in horses with

osteitis or fracture of the distal phalanx may prompt suspicion of soft tissue involvement as well. Although scintigraphy is considered highly sensitive, negative scan findings occur in horses thought to have severe soft tissue injury in the foot. In pool phase images, areas of intense IRU at the dorsal and palmar or plantar aspects of the coronary band are normal, making interpretation of uptake in important structures such as the deep digital flexor tendon (DDFT), navicular bursa, and distal interphalangeal joint difficult.

Pool phase images of the shoulder, thoracolumbar, and pelvic regions are often requested, but we have found them unrewarding. Radiopharmaceutical retention in large vessels, early (within 1 minute) intense uptake in the renal pelvis and urinary bladder, and problems such as distance, shielding, and motion all reduce probability of finding inflamed soft tissue. Pool phase images may be useful in evaluating *acute inflammation* of the DDFT, navicular bursa, superficial digital flexor tendon, suspensory ligament, and digital flexor tendon sheath but may provide negative or equivocal findings if disease is chronic and active inflammation is only mild. Images should be obtained within 4 to 6 weeks after injury to identify lesions within these structures accurately. Pool phase scintigraphic images appear to be less sensitive and specific than ultrasonographic images.

SCAN INTERPRETATION

Qualitative assessment is the most common and useful method for interpreting scintigraphic images. Quantitative assessment such as ROI analysis (comparing the region of one limb with another after considering background values), first-pass, or gaited studies and linear profile studies are easily performed but are time-consuming. However, in mature competition horses quantitative assessment may be essential to confirm relatively small differences in radiopharmaceutical uptake that can be clinically significant. Profile and ROI analyses were useful in determining differences between normal horses and those with clinical signs associated with sacroiliac (SI) joint pain, but considerable overlap in range of RU was seen.^{42,43} An inverse relationship was found between RU in the tubera sacrale and age, and marked left-right asymmetry in quantitative assessment was found in horses with SI joint pain.⁴² Differences in conformation of the sacrum, however, may cause alterations in RU seen both qualitatively and quantitatively, and RU in the tubera sacrale was significantly higher in males.⁴⁴ Images are qualitatively evaluated for *location*, *intensity*, and *character* of RU, and areas of increased uptake (hot spots) or decreased uptake are noted.

Location of Increased Radiopharmaceutical Uptake

Areas of IRU should be accurately identified and located. Is the area of IRU located in cortical or subchondral bone? Cancellous (subchondral) bone located in the epiphyses is normally more active than is bone in the diaphyses, because these regions of bone are larger and have more active bone turnover. A small area of mild IRU in subchondral bone may not be relevant, whereas the same area in the mid-diaphysis of the tibia or the McIII would indicate stress-related bone injury. Any area of IRU, even if small (1 to 2 pixels in width or length), in the cortex of a long

bone is abnormal, but not all areas of IRU are clinically significant.

Is the area of IRU on one or both sides of the joint? Scintigraphic evidence of early OA appears as a focal area of IRU on one side of a joint (see Figure 19-6). Involvement of opposing articular surfaces, determined by evaluating several views, is a negative prognostic sign. If located in the diaphysis, is the area of IRU in cortical or medullary bone? At least two orthogonal images are needed to determine location in the diaphysis. Enostosis-like lesions can appear similar to stress-related bone injury (see Chapters 12, 15, 37, 39, 40, 43, 45, and 47), but prognosis and management decisions differ (Figure 19-9). Focal IRU in horses with well-defined tibial stress fractures can be differentiated from the extensive bicortical involvement seen in horses with severe lameness and potentially catastrophic spiral fractures (Figures 19-9 and 19-10). A rare finding, an authentic fibular fracture, can be differentiated from enostosis-like lesions, soft tissue mineralization, or tibial stress fractures using lateral, caudal, and oblique images. Incidental findings such as an area of IRU associated with calcinosis circumscripta can be spectacular.

Intensity of Increased Radiopharmaceutical Uptake

Areas of IRU are described as mild, mild-moderate, moderate, moderate-intense, or intense. When analyzed using ROI analysis, areas of IRU must have 10% to 15% increased count density to be visually recognized as abnormal compared with surrounding bone or the contralateral limb. When both limbs are abnormal, an obvious difference may not be visible. Experience is critical for accurate image interpretation. In normal horses epiphyseal and metaphyseal areas of bones are more prominent than diaphyseal bone in delayed phase images, because bones are larger and there is generally more bone turnover in cancellous bone. In sound sports horses, demonstrable quantitative variations have been found in RU.⁴⁵ In the front fetlock joint, peak activity was found in the proximal aspect of the proximal phalanx, but in hindlimbs peak activity was found evenly distributed between the distal aspect of the third metatarsal condyles and the proximal aspect of the proximal phalanx.⁴⁵ Comparison using ROI analysis demonstrated that the distal condyles of the MtIII were more active than the distal aspect of the McIII; there were mild differences between right and left limbs, and age had no effect on RU.⁴⁵ In the TB racehorse, qualitative and ROI analysis have shown that in both the front and hind fetlock joints of normal horses there is greater RU in the distal aspect of the McIII or MtIII condyles than elsewhere in the fetlock. In horses with lameness localized to the region there is moderate to intense IRU.⁴⁶ IRU is more common in the medial forelimb and lateral hindlimb condyles.⁴⁶ Because time from injury to imaging is inversely proportional to intensity, IRU associated with fracture may be not intense but only mildly abnormal. Scintigraphic examination in horses suspected of having pelvic fractures may be critical for diagnosis, but expecting to see intense IRU is unrealistic, because background radiation, distance, shielding, and motion compromise image quality. Pelvic fractures are usually not as obvious as fractures in the distal aspect of the limb until muscle atrophy is pronounced. cursory examination of images or placing undue importance on changes in intensity of RU, without considering

Figure 19-9 • **A**, Lateral (left upper and lower images) and caudal delayed phase scintigraphic images of a 2-year-old Standardbred trotter with acute, severe right hindlimb lameness and **B**, lateral (left upper and lower images) and caudal delayed phase images of a 3-year-old Thoroughbred racehorse with acute right hindlimb lameness. Note that in each horse there is focal, intense increased radiopharmaceutical uptake (IRU) in the tibia. In **A**, IRU involves the caudal tibial cortex and is caused by a tibial stress fracture, whereas in **B**, IRU is in the medullary cavity of the tibial diaphysis associated with an enostosis-like lesion. With only one image it would be impossible to differentiate these lesions, but with two images, cortical (**A**) and medullary (**B**) location can be determined.

Figure 19-10 • Lateral (left) and caudal (right) delayed phase scintigraphic images of a Thoroughbred racehorse with severe, nearly non-weight-bearing left hindlimb lameness as a result of a distal spiral tibial fracture. Diffuse moderate-intense increased radiopharmaceutical uptake of the entire distal tibia can be seen in the lateral image, and the spiral nature of the fracture can be seen involving the lateral and medial tibial cortices (arrows) in the caudal image. Radiological findings were negative. Five weeks after imaging, this horse developed a catastrophic fracture of the left tibia and was euthanized. A distinct difference in scintigraphic appearance between this tibia and that shown in [Figure 19-9, B](#) demonstrates the versatility of scintigraphy. Detection of involvement of both cortices of the tibia is a grave scintigraphic finding, and horses are at profound risk for developing a comminuted, displaced fracture.

the nature of uptake, is dangerous. Even if mild and small, focal IRU should always pique the examiner's interest. Images should be evaluated before horses leave the imaging area, because additional 90-degree or 180-degree flexed or other images of the area might give important information. Commonly, advanced radiological changes may be seen in

bone when IRU is only mild, whereas negative or equivocal radiological changes appear in bone when IRU is intense. Radiological evidence of fracture often lags behind scintigraphic changes, an important advantage of using scintigraphy for early diagnosis. Conversely, scintigraphic activity may abate long before radiological changes subside. Scintigraphy measures bone metabolism and can be useful in assessing the current activity of existing radiological changes. Results of all imaging modalities must be interpreted in conjunction with other clinical information. The clinician may judge radiological changes as inactive, or incidental, if a bone scan shows minimal or normal RU (see [Figure 19-4](#)).

Character of Increased Radiopharmaceutical Uptake

Focal IRU means well-localized bone modeling exists, such as that seen with fracture or other substantial bone injury. Even without radiological confirmation, focal IRU should be considered consistent with fracture, particularly in horses in which lameness has been localized to the specific region. In any horse, focal IRU indicates active bone modeling, but intensity of IRU varies with time between injury and scan. Differentiation between focal and diffuse IRU is important. For example, the dorsal cortex of the McIII of TB racehorses undergoes a spectrum of bone changes caused by high-strain cyclic fatigue that can be seen scintigraphically and radiologically. Periostitis (bucked shins) can be differentiated from dorsal cortical fracture scintigraphically, even if accompanying radiological findings are negative ([Figure 19-11](#)). Fracture or traumatic osteitis accounts for most focal areas of IRU, but infectious osteitis or osteomyelitis can look similar. Labeled white blood cell studies using ^{111}In or $^{99\text{m}}\text{Tc}$ can be useful to differentiate infectious

Figure 19-11 • Delayed phase scintigraphic images. **A**, Lateral image of a 4-year-old Thoroughbred (TB) colt with left forelimb lameness as a result of a dorsal cortical fracture (arrow) of the third metacarpal bone (McIII), and **B**, lateral images of both forelimbs of a 3-year-old TB colt with right forelimb (RF) and right hindlimb (RH) lameness after a recent race. Focal increased radiopharmaceutical uptake (IRU) must be differentiated from diffuse IRU and indicates the presence of fracture. Note the continuum of scintigraphic changes in the RF in the horse shown in **B**. Diffuse IRU is diagnostic of periostitis (small arrows) and distally, focal IRU (large arrow) indicates the presence of a dorsal cortical fracture. RH lameness was caused by another stress-related bone injury, an ilial stress fracture (not shown).

processes from other bone injury and are particularly useful when evaluating potential infection after surgery.²⁹ *Diffuse IRU* appears when a large area of cortical, subchondral bone or soft tissue is abnormal, but in horses with diffuse IRU, radiological changes usually are not found. *Generalized IRU* is another term used synonymously with *diffuse IRU*. A moderate, generalized greater RU associated with both sides of a joint than the metaphyseal and diaphyseal regions of long bones may be an incidental finding.

Photopenia is an unusual scintigraphic finding. Theoretically, if blood supply is not adequate during flow and pool phases, radiopharmaceutical concentrations sufficient to delineate normal or abnormal bone are not achieved. Bone infarct, abscess, intense resorption, or sequestration might cause photopenia. Resolution of scintigraphic equipment is not sufficient to see small areas of resorption in dense cortical or subchondral bone, and even if possible to resolve technically, modeling in surrounding bone would obscure, or steal, counts. No known equine disease involves only bone resorption without modeling. Photopenia is seen rarely when portions of bone are surgically removed or displaced out of view. In flow phase images of horses with lameness abolished with palmar digital analgesia there is often reduction of blood flow in the affected limb, recognized as a photopenic region between the coronary band and distal aspect of the foot on dorsal images (Figure 19-12). A relative reduction in blood flow when compared with the contralateral limb may reflect chronic reduction in weight bearing. This finding does not persist in pool phase or delayed images. Although unusual, we have seen a horse with a subperiosteal abscess of the olecranon process of the ulna with photopenia in pool phase images that was thought to be caused by fluid accumulation and

Figure 19-12 • Flow and pool phase scintigraphic images of a 2-year-old Standardbred pacer with acute left forelimb lameness as a result of a suspected subsolar bruise or abscess, but the cause was not confirmed. Note the marked photopenia (arrows) in the flow and early pool phase images that abates later in the scan. Delayed phase images were negative. Photopenia in flow and pool phase images can indicate the presence of infection or ischemia.

compression of nearby vessels, and a horse with photopenia of the proximal aspect of the tibia in delayed phase images caused by severe effusion of the overlying lateral femorotibial joint compartment. In addition, we have seen photopenia in delayed phase images caused by infectious osteitis, bone sequestration, and distal limb ischemia.⁴⁷

General information can be obtained from scintigraphic images and includes an assessment of symmetry, lengths, and conformation. An assessment of the axial

Figure 19-13 • Normal delayed scintigraphic images showing intense physeal uptake in a 2-year-old Thoroughbred in early race training. These areas are normal but may erroneously be interpreted as abnormal (false positive) or may obscure nearby lesions, causing false-negative scans.

skeleton is easily obtained from horses in a standing position, particularly the pelvis, but anatomical information is far inferior to that gained from other imaging modalities (see [Figure 19-4](#)). Pelvic asymmetry (shortened midline-to-lateral pelvic width; position, size, and angulation of the tubera sacrale, tubera coxae, or tubera ischii) can easily be measured even if RU is normal. Obvious abnormalities such as angular deformities, joint hyperflexion or hyperextension, and chronic tenosynovitis of the digital flexor tendon sheath (persistence of IRU in soft tissues seen in delayed phase images) can be documented.

False-Positive Findings

Few false-positive bone scan results occur if the clinician is aware of normal areas of greater RU and if background radiation (bladder, large vessels) is considered. Normally, cortical bone is less apparent than cancellous bone (subchondral), but both are adequately visible in good-quality images. Physeal activity in young horses is pronounced, but normal and many variations exist ([Figure 19-13](#)). Physeal activity decreases with age, but greater RU at the distal radial and tibial physes persists for years. In a study of distal radial physeal closure, radiological closure (24 to 32 months) preceded decrease in scintigraphic activity by several months (mean, 42 months).⁴⁸ In lateral pelvic images the coxofemoral joint (bone stacking of proximal femur and acetabulum) and tubera coxae are always prominent. Additional normal areas of greater RU include the lateral aspect of the metatarsophalangeal joint in plantar images, a bilobed area in the proximal aspect of the tibia in a lateral

Figure 19-14 • Delayed scintigraphic image of the distal part of a forelimb of a 7-year-old Thoroughbred jumper showing focal moderate increased radiopharmaceutical uptake in the dorsal cortex of the proximal phalanx (arrow). This is a normal finding in nonracehorses and may involve one to four limbs.

image of the stifle, the distal lateral aspect of the femur and the proximal aspect of the tibia in a caudal image of the stifle, the proximal aspect of the humerus, the proximal lateral aspect of the radius (radial tuberosity), the pastern joints, the dorsal articular facets of the sixth and seventh cervical vertebrae, the dens, and many places in the skull, such as the temporomandibular joint. In some sports horses such as jumpers, hunters, dressage horses, event horses, timber horses, and driving horses, focal mild to intense IRU is found on the dorsal (most common) or palmar cortex of the proximal phalanx in one to four limbs ([Figure 19-14](#)).

We have been unable to attribute lameness to dorsal cortical IRU and feel it is likely to represent a normal area of modeling, but in 6 of 23 horses lameness was attributed to this site.⁴⁹ In another study of jumping, hunting, and event horses, IRU in the proximal phalanx was considered to be clinically important, but clear differentiation of dorsal cortical IRU from that of the proximal and distal aspects of the bone was not made.⁵⁰ Careful clinical examination and infiltration of local anesthetic solution may help to differentiate this site from other, much more common sources of pain. In the most comprehensive study to date, IRU in the dorsoproximal diaphyseal region of the proximal phalanx was usually bilaterally symmetrical, occurred in 17% of forelimbs and 7% of hindlimbs in older, taller, and heavier Warmblood and Warmblood-cross horses, occurred most commonly in dressage horses and show jumpers, and was not associated with lameness.⁵¹

In dorsal pelvic images the bladder is often superimposed on the sacrum or other pelvic bones and can be mistaken for abnormal IRU. Additional oblique, hemipelvic, or caudal transverse pelvic images should always be obtained. The kidneys are commonly if not always visible in delayed images. The right kidney is more prominent than is the left, because it has a more superficial location and normally accounts for approximately 60% of total glomerular filtration rate.⁵² Diagnosis of renal dysfunction should be made only if gross anatomical derangement is seen and should be confirmed using specific renal function studies and ultrasonographic evaluation. In horses with long-standing hindlimb lameness and muscle atrophy, RU may appear greater in the lame compared with the nonlame limb, a possible false-positive bone scan result.

Perivascular injection or extravasation of radiopharmaceutical can cause obvious, intense IRU in soft tissues at the injection site. If a large volume of radiopharmaceutical is sequestered, distribution is slow, and poor-quality delayed images result. Extravasated radiopharmaceutical can be taken up by caudal cervical lymph nodes, causing interesting but inconsequential IRU. Other nonosseous areas of IRU may be incidental (calcinosis circumscripta, other sites of mineralization, nerve block sites) or clinically important (skeletal muscle).

False-Negative Findings

A false-negative result occurs when the image(s) fails to identify an existing lesion. From a clinical standpoint a false-negative result could be important, particularly in racehorses in which missing a stress-related bone injury could be problematic. In racehorses, in which anamnesis suggests the presence of a stress fracture, a conservative recommendation is prudent even if a negative bone scan finding is obtained. False-negative findings usually result from failing to obtain appropriate images, obtaining poor-quality images, or incorrectly interpreting images. Failure to perform diagnostic analgesia and interpret the clinical relevance of scintigraphic changes may lead to apparent but not authentic false-negative results. Problems with distance, shielding, and motion likely account for many false-negative findings. A false-negative result is possible if a horse with acute pelvic fracture is imaged within 7 to 10 days after injury. False-negative scan results rarely occur in horses with stress-related bone injury, because bone changes are long-standing and resorption and modeling

occur simultaneously. False-negative results have been reported in people undergoing chronic corticosteroid therapy and in those with disseminated metastatic disease, the elderly, and those with osteomalacia or renal osteodystrophy.⁵³ Bone resorption, high osteoclastic activity, and slowed bone turnover may occur with these diseases, although bone modeling usually is present to a certain extent, ensuring a positive result.

Accuracy can be greatly improved by obtaining as many standard and special scintigraphic images as possible (see [Figure 19-5](#)). *A medial lesion cannot be adequately seen using only a lateral scintigraphic image.* Knowledge that the lameness is localized to a specific site can help the clinician carefully evaluate this region by obtaining all possible images, and such targeting can reduce the chance of a false-negative result.

Negative Bone Scan Results

Owners and veterinarians look for scintigraphy to provide the answer to a nagging lameness or performance issue, but in many instances a scan result is truly negative. Every bone scan provides useful and interesting clinical information, regardless of whether the finding is positive or a diagnosis can be made. Negative findings are useful in horses in which an increase in exercise is planned, but care must be taken when giving recommendations in racehorses. Negative findings in any type of sports horse examined for poor performance or a suspected obscure lameness can help clarify the picture. Negative findings on delayed images support clinical information that pain is likely originating from soft tissues. In horses with hindlimb lameness, negative scan findings often lead us to suspect that the stifle may be a source of pain, because delayed images of this region may not be highly sensitive. Findings in horses with chronic proximal suspensory desmitis also are often negative.

Osteochondrosis in Delayed Images

We have identified areas of IRU in weanlings, yearlings, and older horses with osteochondritis dissecans or osseous cystlike lesions, but scintigraphic evidence of bone modeling can be difficult to detect, or it is missed. We have heard anecdotally that some believe osteochondrosis cannot be successfully identified scintigraphically, but our experience suggests otherwise. Intense physeal uptake in weanlings and yearlings is the most important factor in correctly identifying osteochondrosis. Count stealing is certainly important, but so is the possibility that bone modeling around osteochondritis dissecans or osseous cystlike lesions is either minimal or is present at only certain stages. Subchondral bone cysts of the distal aspect of the femur are generally scintigraphically active, but images must be interpreted carefully, and a caudal image of the stifle is mandatory. Osteochondritis dissecans of the shoulder joint involving the glenoid or proximal humeral head usually is scintigraphically active. We have identified several 2- and 3-year-old Standardbreds (STBs) and Warmbloods with large abaxially located extraarticular or small intraarticular plantar process osteochondritis dissecans fragments, or both, of the proximal phalanx in which bone modeling could be seen scintigraphically. Interestingly, in TB racehorses focal IRU in this region is common but does not usually result from plantar process fragmentation.

Osteochondritis dissecans of the lateral trochlear ridge of the femur and the cranial aspect of the intermediate ridge of the tibia is rarely scintigraphically evident.

Artifacts

Urine contamination is particularly prominent in the caudal and plantar aspects of the hindlimbs in fillies and mares. Urine contamination of the bottom of the feet is common, unless boots are applied to the horse before imaging, a procedure that is mandatory if the feet are of specific interest. Alternatively, urine can be washed away and horses can be rescanned. Damage to the collimator or crystal, maladjustment of the photopeak for ^{99m}Tc , deterioration in flood quality, and electrical problems can produce artifacts. Incidental scintigraphic findings have been discussed.

Nerve Blocks

It is reasonable to assume that injections of any type may interfere with interpretation of scintigraphic images. Local or intraarticular injections likely produce short-lived inflammatory changes that may be visible on pool or delayed phase images, but we have found this to be an overrated problem. Low and high palmar analgesic techniques have resulted in IRU seen in pool phase images for up to 17 days after injection, but little effect was seen after palmar digital and palmar (abaxial sesamoid) techniques. No effects of injections were seen in delayed phase images. The authors concluded that although effects were mild, pool phase images should be delayed for 3 to 4 days after palmar digital blocks and 2 weeks after “low” and “high” palmar local analgesic techniques.⁵⁴ We have not found it difficult to interpret pool phase images obtained 24 hours after blocking, if we are aware the horses have been blocked. By using at least two scintigraphic images it will clearly be shown that IRU is at the subcutaneous injection sites and not at important, deeper soft tissues. In most horses, little to no IRU can be seen in pool phase images and no effect occurs on delayed images with one exception. After fibular (peroneal) and tibial and median and ulnar nerve blocks, pool and delayed images show focal RU at the fibular block site and both median and ulnar block sites, respectively, and it is extremely important to know the blocking history and to obtain at least two scintigraphic images. Increased RU is likely caused by local myositis and bleeding (Figure 19-15). Intraarticular injections do not affect delayed images, but they may interfere with pool phase imaging. If pool phase images are critical, evaluation of a joint should be delayed for at least 2 weeks.

INDICATIONS AND CASE SELECTION

Bone scintigraphy is a valuable clinical tool but, like all other modalities, has limitations. Scintigraphy is useful in *early diagnosis* before injuries become radiologically apparent, a finding especially true in horses with subchondral stress-related bone injury, because scintigraphy may identify the problem months or years before radiological findings are positive. Once familiar with scintigraphy the clinician can become comfortable diagnosing fracture without adjunct radiological confirmation. Although fractures are common, scintigraphic findings of other, less obvious lesions must be differentiated and defined. The

Figure 19-15 • Lateral (left) and caudal (right) delayed phase scintigraphic images showing focal increased radiopharmaceutical uptake in what appears in the lateral image as the cranial tibial cortex. In the caudal image, increased radiopharmaceutical uptake clearly involves soft tissue. Cranial tibial stress fractures are not known to occur, but this horse had a fibular and tibial nerve block the day before these images were acquired.

high expectations placed on scintigraphy to provide the lameness answer can be partially met by careful consideration of clinical characteristics of lameness and case selection. We have listed, in decreasing order, the types of clinical situations in which scintigraphy is likely to provide the most information to optimize the chance of answering that tough lameness question. Most important, horses should be lame at the time of the examination, and, when possible, lameness should be localized to a defined region in one or more limbs. Targeted imaging is invariably much more productive than whole-body screening.

Scintigraphy is most valuable in horses with unilateral or multiple limb lameness that has been localized using diagnostic analgesia but in which radiological findings are negative, equivocal, or confusing. In this group of horses, lameness at the time of scintigraphic examination allows for the distinct possibility that bone modeling subsequent to injury will be detected, if indeed bone is the source of pain. Key to accurate interpretation and obtaining all necessary views is localizing the source of pain. Scintigraphy then is most useful in horses that are *lame at the time of examination and for which lameness has been localized*.

Horses that are lame at the time of examination but in which lameness has not been localized comprise the next best group. The importance of lameness at the time of examination cannot be overemphasized. We often scan horses after periods of rest or on returning to training, but if lameness is not apparent, determining clinical relevance of findings is difficult. A subset of horses in which the lower limb has been ruled out by careful diagnostic analgesia makes even better candidates. These are horses in which an upper limb problem such as a humeral, tibial, or pelvic stress fracture may be suspected. These horses are *lame, but although the definitive source of pain has not been identified, the lower limb has been ruled out*.

Horses with an accurate history of high-speed lameness but that are not currently lame are in the next category. These are usually racehorses with stress-related bone injury and strong histories to support that lameness is indeed the cause of poor performance. Performing whole-body scans is most useful in these horses, because compensatory lameness is often present. Lameness may be subtle or difficult to detect during routine lameness examination, and diagnostic analgesia would be difficult to perform. However, this group consists of young, light horses undergoing intense training and racing in which high-strain cyclic fatigue is maximal. In this group then are *racehorses without obvious baseline lameness but in which stress-related bone injury is suspected*.

Scintigraphy is *least* likely to yield a diagnosis in show horses with nebulous histories of gait abnormalities and poor performance and with problems that can be perceived only by the rider. These horses usually are not lame, may have equivocal or negative manipulative test results, and may be difficult horses with which to work. Diagnostic analgesia may be difficult to perform or interpret. In some horses, selective analgesic techniques may improve the feel of the horse, and in some, bilaterally symmetrical lameness may be diagnosed by abolishing pain in one limb and observing lameness in the contralateral limb. Whole-body scintigraphic screening can be frustrating and unrewarding for the clinician and referring veterinarian, but it is occasionally helpful. High-quality images are essential for recognizing subtle abnormalities—for example, in the proximal palmar metacarpal or plantar metatarsal regions, in the foot, thoracolumbar spine, or pelvis. A negative scan result can help direct attention to soft tissues and adjunct evaluation using chiropractic techniques or can result in recommendation of conditioning and exercise intensity changes.

Scintigraphic examination has been used as part of a comprehensive purchase examination, but results must be carefully interpreted and clinical relevance established. Although unusual, this adjunct imaging procedure usually is requested in high-profile, expensive, upper-level sports horses, and results can often be confusing. Finding an upper-level horse of any type without any scintigraphic changes would be unusual, mirroring radiological findings in these horses. Scintigraphy has been found to be useful in establishing clinical relevance of mineralization of the cartilages of the foot, and when present, intense IRU has been associated with radiological changes that could be differentiated (wider and more irregular) from unimportant areas of mineralization or separate centers of ossification,⁵⁵⁻⁵⁷ a possible benefit to clinicians performing examinations before purchase has been proposed.⁵⁵

KNOWLEDGE GAINED FROM SCINTIGRAPHIC EXAMINATION OF THE LAME HORSE

Scintigraphy is a powerful tool for examining a lame horse by which we have been able to give answers, pinpoint diagnoses, study disease progression, and learn about pathogenesis of many lameness conditions. Although we cannot discuss every scintigraphic finding in the lame horse, a few select issues and areas should be reviewed.

Stress-Related Bone Injury in Cortical and Subchondral Bone

Recent studies using scintigraphy and clinical and pathological findings support the concept of a continuum of adaptive and nonadaptive (maladaptive) responses of bone leading eventually to fracture (stress or complete) and OA (see Chapter 100).^{23-25,56,58} Microfracture and callus formation in pelvic bones and the humerus, and prodromal lesions and microfracture in ipsilateral and contralateral limbs of horses with condylar fractures, indicate that pathological changes preceded fracture.²³⁻²⁵ Pathological changes have appeared histologically in subchondral bone of the distal aspect of the McIII, the MtIII and the third carpal bone that preceded overlying cartilage damage, indicating a continuum of changes leading to fracture or OA in racehorses.⁵⁸ Scintigraphic examination of the metatarsophalangeal joint of STBs indicated that the existence of focal IRU in the distal aspect of the MtIII was a common finding in horses in which lameness was localized to this region but in which radiological findings were negative or equivocal.⁵⁹ A continuum of subchondral bone changes has been proposed to account for the later development of fracture or OA, but early changes could be seen only scintigraphically, not radiologically (see Figure 19-6).⁵⁹ Common areas for stress-related bone injury in subchondral bone include the distal aspect of the McIII, the MtIII, the proximal sesamoid bones, and the third carpal bone (Figure 19-16), but we also feel strongly that a continuum of stress-related bone injury could account for development of fractures of the distal phalanx and OA of the distal interphalangeal joint.⁶⁰ Abnormal IRU is common in the lateral aspect of the distal phalanx in the left forelimb and medial aspect of the distal phalanx in the right forelimb, the same sites in which fracture of the distal phalanx is most common in racehorses in North America (Figure 19-17).^{60,61} We know of at least two horses that subsequently developed articular palmar process fracture in these locations.⁶⁰ In nonracehorses, a common finding in those in which lameness is abolished using palmar digital analgesia is focal IRU in subchondral bone of the distal phalanx, corresponding to radiolucent defects and other radiological evidence of OA of the distal interphalangeal joint (Figure 19-18). Observations in racehorses and nonracehorses led us carefully to evaluate medial to lateral hoof balance, because many of these horses were high (longer heel length) on the affected side, strongly suggesting that mechanical forces may be involved in early stress-related bone injury.

Scintigraphic examination has allowed us to demonstrate clinically that a continuum of cortical and subchondral bone changes exists before the development of fracture or OA. This process is better understood and accepted in cortical bone but also occurs in subchondral bone and explains why horses can show lameness without obvious signs of synovitis, because pain originates from subchondral bone without obvious overlying cartilage damage. Cortical and subchondral bone undergo *stress remodeling*, the term used to describe the process by which exercised bone is modeled (new bone) and remodeled (resorption and replacement). Bone adaptation is triggered by changes in number of strain cycles and the magnitude, rate of change, and distribution of strain.⁶²⁻⁶⁴ Adaptive bone remodeling is normal, but exercise may lead to nonphysiological strains,

Figure 19-16 • A, Lateral (left) and dorsal delayed phase scintigraphic images of the right carpus of a Standardbred with stress-related bone injury of the radial facet of the third carpal bone. Focal increased radio-pharmaceutical uptake in the radial facet is a common scintigraphic finding in horses with lameness abolished by middle carpal analgesia but in which other clinical findings are equivocal. **B,** Proximodorsal-distodorsal (skyline) radiographic image of the same horse showing increased radiopacity of the radial fossa of the third carpal bone with mild radiolucent defects within the sclerotic area, a finding consistent with maladaptive or nonadaptive subchondral remodeling (medial is to the right and palmar is uppermost).

or during remodeling, resorption may outpace replacement, and both situations may lead to a nonadaptive response in which damage to cortical or subchondral bone occurs, eventually leading to fracture or OA.^{4,58,60,65} Lameness appears to develop long before radiological evidence of bone damage exists, but during this time scintigraphic examination often reveals focal areas of moderate or intense IRU.

In summary, many common equine lameness conditions, including catastrophic and stress fractures and many forms of OA, result from a continuum of cortical and subchondral bone changes occurring in response to exercise. Scintigraphic examination is the only way to provide early, accurate diagnosis. Single-event injuries occur from direct trauma or acute overload of bone and soft tissue material properties, but they are in the minority in most sports horses with stress-related bone injury. We find it interesting that in the forelimb, with the exception of the distal phalanx, most stress-related bone injuries involve the medial aspect, whereas in the hindlimb most changes

Figure 19-17 • Dorsal delayed phase scintigraphic image of the distal forelimbs in a racehorse showing a common finding of increased radio-pharmaceutical uptake in the lateral aspect of the left forelimb (LF) and medial aspect of the right forelimb distal phalanx. Stress-related bone injury in these locations likely leads to later development of fracture or osteoarthritis.

involve the lateral aspect of the limb. This finding is consistent in TB and STB racehorses and must reflect loading of the limb and commonality of movement rather than the expected effects of counterclockwise racing.

Confusing or Equivocal Radiological Changes

We have often been able to pinpoint diagnosis in horses with confusing or equivocal radiological changes using scintigraphy. Although racehorses with commonly seen areas of stress-related bone injury fall into this category, we have been able to accurately identify sources of pain in other types of sport horses. Navicular disease formerly was a common default diagnosis in horses in which lameness was abolished by palmar digital analgesia. However, scintigraphic examination has allowed us to define 15 to 20 different possible sources of pain in horses with this blocking history. Navicular disease is still a common finding and has been observed to account for part or all of lameness in 65% of nonracehorse sports horses.⁶⁰ Central areas of IRU are most common, and often conventional radiographic images yield negative or equivocal findings. The palmaroproximal-palmarodistal oblique (skyline) view is most useful in identifying subtle radiological changes and should be obtained routinely (see Chapter 30). However, navicular disease should not be the default diagnosis, because OA of the distal interphalangeal and proximal interphalangeal joints, stress remodeling or stress reaction of the distal phalanx, soft tissue pain, and myriad other diagnoses can be made. We recommend the concurrent use of MRI and three-phase scintigraphic examination to help elucidate etiology in horses that have lameness abolished with palmar digital analgesia.^{8,9} Differentiation of lameness in the proximal palmar metacarpal region from that of the carpus can sometimes be difficult from overlap of diagnostic analgesic techniques, but scintigraphy has proved valuable in correctly identifying horses with avulsion injury at

Figure 19-18 • A, Lateral (left) and solar delayed phase scintigraphic images of an 8-year-old large pony with moderate, focal increased radiopharmaceutical uptake (IRU) in the subchondral bone of the distal phalanx (arrows) and early evidence of osteoarthritis (OA) of the distal interphalangeal (DIP) joint. Areas of IRU in subchondral bone can be confused with those at the attachment of the deep digital flexor tendon. Radiographs in this pony revealed an ill-defined radiolucent defect. **B,** Lateral (left) and solar scintigraphic images of a 5-year-old reining Quarter Horse with similar findings in the solar image, but with scintigraphic evidence of advanced OA of the DIP joint in the lateral image. Note the moderate IRU of the dorsal and palmar aspects of the DIP joint in the lateral image. Radiographs revealed extensive changes in both the dorsal and palmar aspects of the DIP joint.

the origin of the suspensory ligament from those with lameness of the middle carpal joint (Figure 19-19). Similarly, lameness associated with the tarsus can be clearly differentiated from that of the proximal metatarsal region. Scintigraphic examination has identified horses with incomplete fractures of the talus, distal tibial subchondral bone injury, fractures of the central and third tarsal bones, and OA of the centrodistal and tarsometatarsal joints. In young racehorses the predominant scintigraphic and radiological changes are seen involving the dorsolateral aspect of the tarsus, unlike what was once thought, that the dorsomedial or medial aspect was most commonly involved (see Figure 44-1). Focal or diffuse areas of IRU are found in the thoracolumbar dorsal spinous processes and may account for clinical signs of back pain, poor performance, or gait restriction but occur only in horses that are ridden

Figure 19-19 • A, Lateral delayed scintigraphic image of the carpus of a horse with a lesion involving the third carpal bone (arrow). **B,** Lateral delayed scintigraphic image of the carpus of another horse with an avulsion fracture of third metacarpal at the origin of the suspensory ligament (arrow). High palmar and middle carpal joint analgesic techniques improved lameness in both horses.

(Chapter 52). However both false negative and false positive results may be obtained. A wide spectrum of scintigraphic and radiological changes in the thoracolumbar spine in horses without back pain has led to the conclusion that IRU in the dorsal spinous processes should be interpreted carefully and in light of other clinical signs; only 7 of 33 horses without back pain had no radiological or scintigraphic abnormalities, and in some horses IRU was pronounced.⁶⁶ We have not identified areas of IRU in the thoracolumbar spine in the STB racehorse, but these are common in young TBs in race training and in most are incidental scintigraphic findings. However, in sports horses scintigraphy may be helpful in the assessment of the clinical significance of radiological evidence of OA of the thoracolumbar facet joints⁶⁷ or spondylosis.⁶⁸ A rare scintigraphic finding in horses with acute forelimb lameness or with acute back pain and respiratory distress is fracture or other injury to a single or two adjacent vertebrae in the midthoracic region.

Confusing Clinical Signs and Unexplained Lameness

Scintigraphic examination has been useful to help explain pain in horses with confusing clinical signs and results of diagnostic analgesia. Lack of localizing clinical findings and negative or equivocal response to intraarticular analgesia prompts scintigraphic examination of numerous TB and STB racehorses each year; the most common scintigraphic abnormality found in these horses with unexplained lameness or poor performance is subchondral bone injury of the McIII or the MtIII condyles (Figure 19-20). Horses with early OA with pain originating primarily from subchondral bone do not consistently improve with intraarticular diagnostic analgesia. Likewise, horses with advanced OA do not

Figure 19-20 • **A**, Lateral (*left*), plantar, and flexed lateral delayed phase scintigraphic images of a 4-year-old Thoroughbred racehorse with maladaptive or nonadaptive subchondral bone remodeling of the distal aspect of the right third metatarsal (MtIII) condyle. Note the focal, moderate-intense increased radiopharmaceutical uptake (IRU) of the distal lateral aspect of the MtIII. **B**, Pool phase (*left*) and delayed phase lateral (*second from left*), dorsal, and flexed medial (*right*) scintigraphic images of an 11-year-old Arabian sports horse with severe osteoarthritis of the left metacarpophalangeal joint (MCPJ). Note the unusual but ominous IRU (*arrow*) in the palmar pouch of the MCPJ in pool phase images that persists in delayed phase images. **C**, Lateral (*left*) and plantar delayed phase scintigraphic images of a 5-year-old Standardbred pacer with right hindlimb lameness abolished with plantar digital analgesia. Expecting to find a lesion in the foot, we saw focal, intense IRU in the proximal aspect of the proximal phalanx consistent with a midsagittal fracture. Pain in the metatarsophalangeal joint can be abolished with plantar digital analgesia.

reliably improve with intraarticular analgesia, a finding that has prompted referral of a small number of horses in which an unusual and consistent scintigraphic abnormality of the fetlock joint was found (see [Figure 19-20](#)). Accumulation of radiopharmaceutical in subchondral bone (most commonly the distal aspect of the McIII or the MtIII and the proximal phalanx) in combination with areas of IRU in the palmar or plantar pouch of the fetlock joint is diagnostic for end-stage OA, an ominous scintigraphic finding. We have imaged racehorses in which forelimb or hindlimb lameness was abolished using palmar or plantar digital analgesia and that were suspected of having a lesion in a foot. Radiological examination of the feet was negative. Three-phase scintigraphic examination revealed IRU in the fetlock joint demonstrating clearly that palmar or plantar

analgesia can indeed abolish pain in more proximal locations in the limb. Midsagittal fracture of the proximal aspect of the proximal phalanx (see [Figure 19-20](#)), fracture of the distal condyles of the McIII or the MtIII, and fracture of the proximal sesamoid bones are most commonly found. We have examined 20 horses with IRU in the rib(s) and in some, clinical signs of forelimb lameness (ribs 1 to 3), resistance to saddling, or poor performance could be explained by fracture, anomaly, or injury of ribs, clinical answers that could not have been provided without scintigraphy.⁶⁹ We examined two horses with IRU in distal or proximal diaphyseal and metaphyseal bone and radiological evidence of periosteal new bone formation and diagnosed hypertrophic osteopathy, but the primary cause was never found. It is possible these horses had bone fragility disorder, a recently described syndrome of horses in California.^{70,71} Unexplained lameness and numerous sites of IRU of the axial and proximal portion of the appendicular skeleton were found in 16 horses, particularly the scapula (13) and ribs (11), and horses had unusual clinical signs such as scapular bowing, but the cause remains undetermined. Pulmonary silicosis was incriminated in one report but affected only 4 of 16 horses in another.^{70,71} Scintigraphy provided vital clinical information.

Lameness Related to the Pelvis

Good-quality scintigraphic images of the pelvis can obviate the need to obtain radiographs with horses under general anesthesia. Image quality can further be improved using motion correction software (see [Figure 19-4](#)). Horses with IRU of the coxofemoral joint often have distant areas of IRU, a scintigraphic finding that worsens prognosis for future soundness. In two horses in which scintigraphy identified single or multiple areas of IRU, fracture of the pubic symphysis, not identified in either horse scintigraphically, was found at necropsy examination in addition to those areas properly identified.⁷² Although horses seemingly have one predominant source of lameness, with pelvic injury scintigraphic identification of additional sites is an important negative prognostic sign. False-negative results are also possible. Pelvic stress fractures, fractures or enthesopathy of the third trochanter and tubera ischii, sacroiliac injury, direct trauma to the tubera coxae, and fractures of the tail head and caudal aspect of the sacrum have been identified as causes of obvious to subtle signs of hindlimb lameness (see [Chapters 50 and 51](#)). We have seen very few horses with authentic abnormalities of the sacroiliac joints, but Dyson and colleagues have documented the importance of careful scintigraphic and clinical examinations of this region.^{42,43}

Damaged Skeletal Muscle

Damaged skeletal muscle behaves like damaged bone. Areas of IRU in skeletal muscle appear in *delayed images* and rarely in pool phase (soft tissue) images. We have observed two distinct patterns of IRU in skeletal muscle. Most commonly, generalized IRU in the gluteal and epaxial muscles appears in racehorses, but can also be seen in sports horses, and is thought to be consistent with previous exertional rhabdomyolysis. Occasionally, IRU appears concomitantly in the latissimus dorsi muscle and rarely in the triceps muscle. In these horses, creatine kinase and aspartate transaminase enzyme concentrations usually are only

mildly elevated. In the original report, IRU in skeletal muscle was seen 24 hours after horses underwent strenuous exercise on a high-speed treadmill, and the authors suggested that imaging should be performed within 24 to 48 hours of exercise.⁷³ Our experience is different, however, because we have seen generalized IRU of skeletal muscle in horses that have trained at least 7 to 10 days before scintigraphic examination. Of 129 horses with scintigraphic abnormalities of the pelvis, 34 had IRU in skeletal muscle.⁷² Lameness associated with IRU in skeletal muscle was not apparent, but abnormal IRU in muscle was thought to explain a portion of the horse's poor performance.⁷² However, not all horses with previous exertional rhabdomyolysis have scintigraphic abnormalities.

In the less common second form, IRU appears in individual muscles or portions of muscles. The hindlimb is most commonly affected, and individual portions of the biceps femoris, semitendinosus, or gluteal muscles are

abnormal. Although this form is most common in racehorses, occasionally epaxial or gluteal IRU is identified in nonracehorse sports horses. Although horses may show pain on palpation of the affected region, we have not been able to identify these areas as the cause of hindlimb lameness. Elevated levels of creatine kinase and aspartate transaminase are not found. Horses with this form of IRU in muscle usually are lame in the ipsilateral hindlimb but from a distally located site. We have speculated that muscle strain or tearing may have occurred from altered limb carriage resulting from the primary lameness condition. However, one of the Editors (SJD) has recognized IRU in the gluteal, biceps femoris, or psoas muscles in association with elevated levels of creatine kinase and aspartate transaminase in sports horses that was believed to be the primary cause of lameness or poor performance. Rarely, we have identified IRU in a forelimb involving subclavius, pectoral, or triceps muscles.

Chapter 20

Computed Tomography

Sarah M. Puchalski

PHYSICS

Computed tomography (CT) is a well-established diagnostic imaging modality that has been in clinical use in medicine for several decades but only recently has become commonly used in veterinary medicine. The essential concept of a CT scanner is that an x-ray-generating tube is positioned across from a row of digital x-ray detectors in a circular gantry. The tube and detectors spin around the outside of a horse, creating a continuous radiographic image through 360 degrees. The detectors are linked to a computer system that manipulates the imaging data by a process called *back projection*, thereby generating cross-sectional images based on the subject density.¹

EQUIPMENT

CT hardware, like most imaging technology, has undergone extensive revision since its inception. One of the most important advances in CT hardware was the advent of the slip ring, allowing for helical scanning. With helical scanning, the x-ray tube and detectors continuously spin around the horse while it translates or moves through the center of the gantry. The resultant path of the x-ray tube relative to the horse is helical, giving the technique its name. Another, equally important, major advance is the advent of multislice technology. Multislice CT is a modification of the aforementioned basic configuration whereby multiple detector rows are positioned opposite the x-ray generator. The x-ray generator exposes the subject, and the transmitted x-rays are detected by several rows of detectors on the opposite side of

the gantry. Since the first appearance of a dual-slice CT scanner, this technology has burgeoned, and now up to 256-slice scanners are available. The number of detector rows determines the number of images that can be acquired per rotation of the gantry components, meaning that a four-slice scanner can acquire four images per rotation.

In order for horses to be imaged, careful consideration must be given both to the design of the CT table and to the size of the CT gantry opening. The CT table must not only support the weight of the horse but also move with speed and great precision. For a single-slice helical scanner acquiring 1-mm-thick images, the horse must move 1 mm per rotation of the gantry, which generally occurs in about 0.8 seconds. In order to accomplish this, equine CT tables have been custom-designed to work with those manufactured for scanning people. More recently, commercially available equine CT tables have come onto the market (Figure 20-1). An alternative style of CT scanner has recently resurfaced as

Figure 20-1 • Commercially available equine table attached to a four-slice helical computed tomography scanner. (Phillips, the Netherlands.)

an option for horses. This type of CT gantry can be equipped with multislice capabilities and is portable. The gantry translates around the outside of the horse with the requisite precision and speed. CT scanners have been built for human applications and as such typically have a circular gantry opening of around 70 cm, which determines the maximum size of the patient or area to be scanned. Currently scanners with 30- to 35-cm openings are commercially available and are appropriate for equine extremity work. There is a movement toward larger gantry sizes that will likely result in machines with >80-cm openings becoming available in the near future, which should increase the clinical utility of equine CT to include larger anatomical regions.

IMAGE DISPLAY AND PROCESSING

Image Display

CT images map tissue density in the subject. Each pixel in the two-dimensional CT image actually represents a volume of tissue or volume element (voxel) defined by the pixel size in two dimensions and slice thickness in the third dimension. Typical slice thickness ranges from 1 to 10 mm, and now with multislice scanners, images less than 1 mm thick can be obtained. For each voxel, a value is recorded in Hounsfield units (HU) or CT units. This numerical value represents the density of the tissue within the voxel relative to water, which is arbitrarily set to equal zero. Density values of common tissues are listed in **Box 20-1**. Lesions can be described as hypodense or hyperdense.

The viewer, using routinely available image review software, can reversibly manipulate the displayed grayscale value of the tissues. Using a wide “window width” is appropriate for the evaluation of tissues with a wide density range such as bone (approximately 400 to 1500 HU). Viewing with a narrow window produces higher image contrast and is appropriate for the evaluation of tissues with a narrow density range such as soft tissue (approximately 40 to 120 HU). “Level” is to the midpoint of the grey shades that are displayed. Changing the level increases or decreases the brightness of the image. In order to perform a complete and thorough evaluation of CT images, the viewer should actively manipulate both window width and level to view all tissues (**Figure 20-2**).

Image Processing

Image processing refers to mathematical manipulation of the images and is most often performed in the background at

the time of acquisition. Processing is used to improve the appearance of an image or help the viewer to better evaluate one type of structure such as soft tissue versus bone (see **Figure 20-2**).²

Image Reconstruction

Image reformatting and reconstruction are routinely used to manipulate the imaging data to appear differently. Image reformatting is the simplest form of reconstruction and is the process by which the viewer can “reslice” the imaging information into a different orientation (**Figure 20-3**). The resultant images are two-dimensional cross-sections of anatomy. The quality of the reconstructed images is highly dependent on the original slice thickness and the slice interval. Thinner slices that overlap result in better images than thicker slices or slices that do not overlap. Helical scanners are capable of producing overlapping slices, and multislice scanners can acquire images that are less than 1 mm in thickness.

Three-dimensional (3D) reconstructions use the voxel density value (HU) to create models that represent anatomy in a completely different format. Two commonly used types of 3D reconstructions are termed *surface rendering* and *volume rendering*. In a surface-rendered image, the viewer selects a minimum density threshold so that only tissue of higher density than the threshold is displayed. This technique can be useful to create a topographical impression of a fractured bone. Volume rendering uses the same principle, but a color scheme is used to depict tissues within a specific density range. The resultant image depicts the color-coded structure from whichever external viewpoint the viewer chooses. **Figure 20-4** shows an intraarterial CT angiogram, viewed from the palmaromedial aspect, in which the operator has progressively increased the minimum threshold so that all tissues of lower density are removed. The final image has a threshold of about 550 HU, and only the surface of the bone and the contrast medium within the major vessels are visible.

Contrast Media

Contrast media are available for all diagnostic imaging modalities and are used to better identify or more thoroughly characterize either normal or abnormal structures. Routine radiographic contrast media (barium or iodine based) can be used to augment the clinical utility of CT. Most commonly, iodine-based injectable contrast media are given by the intravascular route to identify regions of increased blood flow or vascular permeability, as expected with injured or inflamed soft tissues. Regional intraarterial administration with concurrent CT scanning has been described to aid in the identification of soft tissue lesions of the foot.^{3,4} This technique is also useful for regions higher in the limb—for example, to evaluate the suspensory ligament of both forelimbs (see **Figure 20-2**) and hindlimbs and the structures within the carpal canal. In the early phases of tendon and ligament injury, contrast medium is present in increased quantity because of extravasation from abnormally permeable blood vessels. As a lesion heals, neovascularization develops; contrast medium is seen within small-caliber blood vessels.⁵ Alternatively, nonionic iodine-based contrast media can be injected into synovial spaces to surround and improve margin visibility of structures in or around joints, sheaths, and bursae. This

BOX 20-1

Density Values of Different Tissues

Tissue	Density (Hounsfield Units [HU])
Gas	−1000
Fat	−120
Water	0
Muscle	40
Equine DDFT	90–120
Medullary bone	400–600
Cortical bone	1500

DDFT, Deep digital flexor tendon.

Figure 20-2 • Transverse computed tomography images all acquired at the same location in the proximal metacarpal region, but processed and displayed differently. Medial is to the left. **A** has a wide window width and has been processed with an edge-enhancing algorithm to enable accurate assessment of bone. **B** has the same window, but a smoothing algorithm has been applied for evaluation of the soft tissues. **C** is a soft tissue algorithm with a narrow window width. **D** is the same location after the regional administration of contrast medium. This horse has suspensory ligament injury that is moderately contrast enhancing with associated entheous and endosteal new bone at its origin. Note the irregular contour of the palmar cortex of the third metacarpal bone, seen best in **A** and **B**, and the periarticular osteophyte bridging the articulation between the second and third metacarpal bones. In **C**, note the hypodense areas in the suspensory ligament corresponding to areas that show contrast enhancement in **D**. The superficial and deep digital flexor tendons and the accessory ligament of the deep digital flexor tendon have uniform density.

allows for the evaluation of intraarticular ligaments (stifle, carpus) or the identification of adhesions (navicular bursa) or cartilage lesions. The systemic use of contrast medium in horses is impractical because of the large dose required and time-consuming administration.

CLINICAL APPLICATIONS

Fracture Assessment

CT's greatest strength is the detailed evaluation of osseous structures. The elimination of superimposition allows the viewer to detect small changes in bone density caused by osteolysis or proliferation that would go unnoticed on routine radiographs. This also applies to the detection of small fragments or comminuted fracture lines. These characteristics make CT an ideal choice to accurately characterize fractures, in order to establish prognosis or for preoperative planning. CT is particularly useful in evaluating fractures

when they occur in complicated anatomical regions such as the carpus or tarsus (Figure 20-5). CT intraarterial angiography of the extremity can be performed to identify concurrent soft tissue and blood vessel trauma.

Lameness Diagnosis

The goal of diagnostic imaging is to accurately identify and thoroughly describe pathology. All diagnostic imaging techniques should be considered in the light of these goals. In some horses, it is difficult to identify lesions and to thoroughly describe underlying pathology using radiography and ultrasonography, the more routinely available imaging techniques. Advanced imaging should be used when either one of these goals is not met. In lameness diagnosis, advanced diagnostic imaging techniques will usually augment a clinical workup by providing additional or different information. The clinician must carefully evaluate each horse, weigh the cost-benefit ratio, and decide if

additional diagnostic techniques are necessary to solve the clinical problem. Although CT scanning is rapid, limitations exist. CT should be used once the source of pain causing lameness is established, because it is largely impractical to “screen” numerous anatomical regions. Furthermore, general anesthesia, with its associated risks, is necessary in most horses to obtain high-quality diagnostic images.

At the Veterinary Medical Teaching Hospital of the University of California, Davis, the most common indication for using CT is the evaluation of lameness caused by

foot pain. The addition of regional contrast medium improves the ability of CT to detect some of the commonly reported soft tissue injuries that occur deep within the hoof capsule. Lesions of the deep digital flexor tendon (DDFT) (Figure 20-6), and collateral ligaments of the distal interphalangeal joint, navicular bursa, collateral sesamoid-equin ligaments, and distal sesamoid impar ligament are identified with similar frequency as those identified using magnetic resonance imaging (MRI).^{6,7} Only a few equine studies exist that directly compare CT with MRI in horses with foot pain.^{8,9} Recent studies show that contrast-enhanced CT compares favorably with MRI and pathology for the identification of DDFT lesions within the hoof capsule.^{10,11}

CT is useful to identify conditions of bones and soft tissues, and its use is limited only by the physical configuration of the gantry and the size of horses. Most 70-cm gantry scanners are able to image up to the level of the distal diaphysis of the radius and tibia. CT is invaluable when routine diagnostic techniques are unable, because of inherent limitations of the technique, to thoroughly investigate an anatomical region. Valuable clinical information is gained from CT evaluation of subchondral bone, particularly the fetlock joint (Figure 20-7), the carpus and tarsus, and the origin of the suspensory ligament in both the forelimbs and hindlimbs (see Figure 20-2) and for evaluation of intracapsular soft tissue injury in the stifle. Contrast medium given through an intravascular route provides additional information about the underlying physiology of soft tissue structures. Tendon and ligament lesions appear hypodense, heterogeneous, and enlarged on plain CT, similar to other imaging modalities. After the administration of contrast material, soft tissue lesions typically enhance and appear hyperintense, thus helping the viewer to identify and characterize the abnormalities. CT is useful in regions where ultrasonographic evaluation is restricted by regional anatomy, such as the foot, carpal canal, or distal sesamoid ligament attachments. Contrast medium administered into a synovial structure outlines the structures in contact with the synovial fluid. This has been particularly useful in the evaluation of

Figure 20-3 • Tranverse computed tomography images on the right (medial to the left) correspond to the levels shown by the white lines on the sagittal plane image on the left, which is reformatted from the original series. A medial lobe lesion is present in the deep digital flexor tendon (DDFT) in the pastern (arrow), and biaxial dorsal lesions are present in the DDFT in the heel region, characterized by hypodense foci (arrows) and navicular bursa effusion laterally (*).

Figure 20-4 • Three-dimensional volume-rendered images of a computed tomography angiogram. The operator has progressively increased the threshold from left to right. On the left, most of the soft tissues including the hoof capsule can be identified. Extending to the right, the soft tissues disappear first, followed by the hoof capsule and then the small-caliber laminar blood vessels. On the image on the right, only the larger blood vessels containing contrast media and bone surface are visible. This horse has erosion of the flexor cortex of the navicular bone.

Figure 20-5 • Three images from a horse that sustained carpal fractures. **A** is a dorsal 15-degree lateral-palmaromedial oblique radiographic image cropped to show fractures with mild displacement in the fourth carpal bone. **B** is a transverse computed tomography image at the level of the proximal row of carpal bones showing palmar, comminuted fractures of the intermediate carpal bone (ICB). **C** is obtained through the distal row of carpal bones. Marked fragmentation of the fourth carpal bone (C4) and a fracture of the lateral and dorsal aspects of the third carpal bone (C3) are present.

Figure 20-6 • Transverse computed tomography (CT) images obtained at the level of the middle phalanx. **A** is a precontrast CT image, and **B** is an image obtained during an intraarterial infusion of contrast medium. A lesion (arrows) is present in one lobe of the deep digital flexor tendon. It is heterogeneous and hypodense on precontrast images (arrow) but has new vessel formation resulting in contrast enhancement of the lesion after contrast medium has been administered (arrow). There is also irregular enhancement of the synovium of the dorsal aspect of the distal interphalangeal joint (*).

intraarticular soft tissue structures such as the cruciate and meniscal ligaments and the menisci of the equine stifle.¹² Arthrography also permits an indirect evaluation of the overlying articular cartilage. This can be effective in locations inaccessible to direct observation using arthroscopy.

Laminitis Evaluation

The role of CT in evaluating horses with laminitis has yet to be defined. The addition of intravascular contrast medium provides an unobstructed view of regional vasculature (see Figure 20-4). High bone detail provides an excellent way to evaluate the distal phalanx and its response to laminitis. Furthermore, quantitative techniques using dynamic contrast-enhanced CT for the measurement of

blood flow have been developed and may play a role in evaluating horses with laminitis and in research studies.¹³

Interventional Computed Tomography

CT is able to accurately image metallic structures and can therefore be used to guide procedures. Most commonly this technique is used to guide the needle placement for tissue or fluid sampling or in therapeutics, such as for the delivery of medication. Intralesional medication can be accurately delivered to those structures inaccessible to ultrasonographic guidance such as the DDFT within the hoof capsule. CT is used to guide surgical procedures such as debridement of the distal phalanx, partial hoof wall resection, and subcapsular mass removal from the hoof.

Figure 20-7 • Computed tomography images from a horse with subchondral bone injury of the distal aspect of the third metacarpal bone and periarticular osteophyte formation of the metacarpophalangeal joint. **A** is in a dorsal plane, **B** is in a transverse plane, and **C** is in a sagittal plane. **D** is a three-dimensional reconstruction with the opacity of the proximal phalanx reduced to show the articular surface of the distal aspect of the third metacarpal bone (McIII). In **A**, **B**, and **C**, note the hypodense areas in the subchondral bone of the dorsal aspect of the medial condyle of the McIII.

ADVANTAGES AND DISADVANTAGES

Advantages

CT scanning is more rapid than high- and low-field MRI. This has several benefits. General anesthesia time is minimized, and imaging sequences can be performed during a breath hold to prevent image degradation by respiratory motion. Rapid scanning allows for the concurrent administration of contrast medium. Contrast medium allows the clinician to evaluate the soft tissues and underlying pathophysiology. The contrast-enhancing pattern of tendons and ligament lesions changes over time, and it is possible that this characteristic can be exploited to monitor lesion progression or regression. The ability to characterize bone morphology using CT far exceeds that achieved using planar modalities such as radiography and nuclear scintigraphy. Metal can be imaged using CT, so interventional procedures can be guided, thereby extending CT from a

diagnostic to a therapeutic technique. Lastly, CT scanners are more affordable than high-field MRI scanners, yet provide high-quality images.

Disadvantages

CT does not provide information regarding bone activity or bone fluid accumulation, unlike nuclear scintigraphy and fluid-sensitive MRI sequences (STIR). This information can be inferred by evaluation of the imaging characteristics such as irregular bone margination that likely represents a higher level of activity. CT images of soft tissue structures have less image contrast when compared with high-field MRI, making small lesions of tendons and ligaments more difficult to identify. CT does require special facilities and trained personnel, and although the availability of CT is increasing, it still is available only in referral and university hospitals.

Chapter 21

Magnetic Resonance Imaging

Rachel C. Murray and Sue J. Dyson

Magnetic resonance imaging (MRI) is a method of imaging that can allow examination of both osseous and soft tissues

with detailed anatomical resolution and also provides some physiological information. Advances in technology during the past 10 years have made it possible for MRI to become a practical diagnostic tool in both anesthetized and standing horses (Figures 21-1 and 21-2).¹ Use of MRI has revolutionized our understanding of foot pain in the horse and has considerably improved understanding of other types of lameness further proximally in the limb.²⁻⁵ As a result, MRI is increasingly being used for diagnosis of orthopedic disorders in equine practice and can add considerable information to a diagnostic investigation. However, as with any imaging technique, MRI is only useful in the context of the entire clinical picture and

Fig. 21-1 • The 1.5-T GE Echosped (General Electric Medical Systems, Milwaukee, Wisconsin, United States) magnet at the Animal Health Trust (Newmarket, United Kingdom) is used for MRI of horses under general anesthesia. Located in the bore of the magnet is a radiofrequency coil suitable for use on the equine distal limb. Both limbs are placed into the magnet bore. A specially shaped pad allows the coil to be placed only over the limb being imaged and in the center of the magnet.

Fig. 21-2 • The Hallmarq (Hallmarq Veterinary Imaging, Guildford, United Kingdom) 0.29-T MR system at the Animal Health Trust (Newmarket, United Kingdom) is used for MRI of horses under standing sedation. This horse is undergoing MRI of the carpus.

needs to be interpreted in light of other diagnostic findings. Terminology is sometimes confused: magnetic resonance (MR) refers to the absorption of energy exhibited by particles (as atomic nuclei or electrons) in a static magnetic field when the particles are exposed to electromagnetic radiation of certain frequencies. MRI refers to a noninvasive diagnostic technique that produces computerized images of internal body tissues and is based on nuclear magnetic resonance of atoms within the body induced by the application of radio waves.

PRODUCTION OF MAGNETIC RESONANCE IMAGES

MR images are produced through interactions between a strong magnet, a radiofrequency (RF) coil, magnetic field gradients, and powerful computing facilities. MR images are based on the spinning motion of MR active nuclei (nuclei with an odd number of protons). Hydrogen nuclei are used in clinical MRI because they are abundant in the body and are particularly mobile in fat and water. When a horse (or body part) is put into the magnet, the MR active nuclei align parallel or antiparallel to the static magnetic field. To produce an image, an RF wave at a specific frequency (dependent on the magnet field strength and the MR active nuclei selected) is applied at 90 degrees to the static magnetic field, B_0 . This gives energy to the hydrogen nuclei, which then spin faster and alter the net magnetization vector away from the static magnetic field. When the RF wave terminates, energy is lost from the excited hydrogen nuclei, either to the surrounding environment (spin-lattice or T1 relaxation) or to adjacent nuclei (spin-spin or T2 relaxation), and the net magnetization vector returns to zero. This energy loss is detected by the receiver as MR signal. The signal is then converted to a digital image using complex computer software. Each pixel within the matrix has a particular signal intensity, and the accumulated pixels make up the final image.

Magnets may be considered high-, mid-, and low-field strength, with field strength measured in Tesla. Magnetic field homogeneity is important in production of good quality images. RF coils are made to surround the region of interest with as little space between the coil and the area of interest as possible to maximize signal detection. They may be both a transmitter (transmits the RF waves) and receiver (detects the MR signal produced). The magnetic field gradients are used to place the MR signal in space. This is achieved by generating short-term spatial variation in magnetic field strength across the horse (or body part). There are three sets of gradient coils, each oriented in a different direction. Repeated application of large electrical current pulses results in the gradient coils making a loud noise during scan acquisition, especially at higher field strengths.

A pulse sequence includes a defined series of RF waves, gradient maneuvers, and signal detection. The repetition time (TR) defines the time between repetitions, and the echo time (TE) defines the time between the RF pulse and detection of the echo (MR signal). Selection of pulse sequence determines the image contrast and appearance of particular tissues.

Images are produced in a gray scale with the contrast defined by the particular pulse sequence used for image acquisition, the imaging parameters, and the properties of the tissue being imaged. Information is acquired as tomographic slices, so the orientation and thickness of slices (or three-dimensional [3D] volume datasets) can be varied and defined.

Generally a pilot scan with wide slice thickness is performed in three planes, and further image sequences are oriented and positioned relative to the pilot scan. It is normal practice to acquire images in three planes: sagittal, dorsal (coronal), and transverse (axial).

A complete MRI scan of a horse usually includes a series of different pulse sequences, the choice of which is

determined by the operator. The tissues being examined, the suspected pathology, and the type of MRI system influence the selection of pulse sequences. For horses, the choice of sequence is also influenced greatly by time constraints to minimize risk of movement in a standing horse and limit time under general anesthesia.

Various manipulations during image acquisition can be used to look at particular features of tissues, such as fat suppression techniques to identify pathology in medullary bone. Intravenous administration of gadolinium contrast medium can be used to demonstrate blood flow, perfusion of a suspect area, or to investigate damage to the blood-brain barrier. Postprocessing manipulations can be used to reorient images acquired in an oblique orientation; to measure size, area, or volume; for motion correction; or to further understand signal intensity patterns.

EQUIPMENT FOR MRI IN HORSES

MRI can be performed in horses using various different types of systems. High-field closed systems are similar to those used in many human hospitals. These units have a superconducting, helium-cooled magnet in a cylindrical configuration into which the area of interest of the horse has to be squeezed; thus the horse needs to be under general anesthesia, and a team of operators is required to position the horse (see Figure 21-1). There are low-field open MRI systems that also require horses to be imaged under general anesthesia but have fewer restrictions on space; therefore it may be easier to position the horse into the imaging portion of the magnet. A low-field MR system for the standing horse has been developed specifically for the equine market, which has allowed images to be acquired with horses under sedation (see Figure 21-2). Use of motion-insensitive imaging sequences helps to account for slight sway that may occur during sedation. Time for image acquisition is generally longer in low-field units for the same or less resolution and image quality as a high-field system; thus horses may require sedation or general anesthesia for more prolonged periods to acquire images of the entire region required.

For the MRI systems available, in general the areas that can be imaged in the adult horse are limited to the head and cranial aspect of the neck, the forelimb up to and including the carpus, and the hindlimb up to and including the tarsus, although images of the stifle can also be obtained in a few systems in horses of suitable size and conformation.⁶ In a foal, it may be possible to place the entire body into the magnet in a high-field closed or low-field open system.

ADVANTAGES AND DISADVANTAGES COMPARED WITH OTHER IMAGING TECHNIQUES

Advantages

MRI is more versatile than most other imaging modalities because of its ability to provide images sliced in many planes and 3D images in a variety of orientations. Like ultrasonography and radiography, MRI has the ability to provide anatomical information, but MRI also has a physiological sensitivity like that of nuclear scintigraphy.

MRI is the only method presently available that can assess all tissues during a single examination. Ultrasonography is extremely useful for imaging soft tissues but is

impractical in a number of areas and cannot be used to assess the internal structure in bones. MR technology allows imaging of those soft tissue structures that are inaccessible with ultrasonography. Radiography shows mineralized tissues but is less sensitive than MRI because each image is obtained through the full thickness of the area, and only the orientation selected can be assessed; therefore small abnormalities may be missed. In contrast, MR images can be obtained in multiple planes without loss of image quality, and data can be assessed in slices so that the image is not limited to a summation through the entire structure. MRI has been shown to be more sensitive to pathological conditions of bone and tendons than radiography and ultrasonography, respectively.

Like MRI, computed tomography (CT) can be used in horses for accurate assessment of the 3D distribution of pathological conditions of the bone, particularly in relation to fracture configurations. Some soft tissue detail is also demonstrated with CT but generally with inferior contrast. In contrast to CT, articular cartilage can generally be assessed using MRI without use of invasive arthrography, and bone pathology without fracture may also be better evaluated with MRI. Arthroscopy is the standard of reference for the evaluation of articular cartilage, but it cannot assess deep chondral lesions and lesions of the subchondral bone.

Disadvantages

Initially the greatest disadvantages of MRI were the expense of the equipment and the requirement for general anesthesia. However, as advances in technology have reduced the costs and made it possible to obtain images in a standing horse, these problems have increasingly been resolved. Unfortunately, MRI remains limited to areas that can be placed within the magnetic field; thus the caudal aspect of the neck, the trunk, and the proximal aspects of limbs of adult horses cannot yet be imaged, but it is possible that with advances in technology, these problems may also be overcome. Until recently, unlike CT, MRI could not be used for image-guided injections because ferrous metal cannot be used within the magnet; however, MR-compatible needles have now become available.

INTERPRETATION OF MAGNETIC RESONANCE IMAGES

An understanding of MRI, a detailed knowledge of anatomy, and considerable experience are required to interpret MR images reliably. The wide range of normal anatomy within the horse population means that experience in reading equine images and use of concurrent clinical diagnostic evaluation are crucial for determining the clinical significance of a potential lesion. Lesions that may be detectable using MRI but are difficult to detect with other imaging modalities include ligament and tendon injuries (within the hoof capsule), occult fractures, articular cartilage damage, bone trauma and necrosis, osseous cystlike lesions, subchondral bone modeling, and space-occupying lesions.⁷ Interpretation is improved by assessing T2-weighted, T1-weighted and/or proton density, and fat-suppressed images at each site.

Image contrast is determined by tissue proton density, T1 and T2 relaxation, and by pulse sequence and imaging

parameters, which also determine the T1 and T2 weighting of the image. Clinical MRI uses hydrogen nuclei as the MR active nuclei that create the signal; thus the appearance of a tissue on MRI is determined by the density and mobility of the hydrogen nuclei it contains and their relaxation properties after excitation (when the signal is created). Images of tissues can be weighted to show proton density and T1 and T2 relaxation properties of the tissues. Tissues where the hydrogen nuclei are tightly bound have low signal intensity (black) on proton density, T1-, and T2-weighted images; for example, cortical bone or tendon. In contrast, water and fat contain highly mobile hydrogen nuclei and can produce considerable signal. However, water has high signal intensity (white) on T2-weighted images but low signal intensity (black) on T1-weighted images. Therefore each tissue has a characteristic signal intensity pattern on MR images, so with experience, normal tissues can be clearly identified (Figures 21-3 and 21-4).

The MR properties of a tissue are altered by damage, and the stage of damage and healing may be determined by differences in signal intensity patterns and the shape and size of different structures. This makes it possible to use MR images to evaluate tissue normality and the type, severity, and stage of injury in tissue damage.

Pathological processes are frequently associated with increase in free water within and around the affected tissues, which can be easily detected with MRI. These changes generally lead to an increase in signal intensity on T2-weighted images and a decrease in signal intensity on T1-weighted images. These changes may be most easily seen on T2-weighted images. However, the combined information from T2-, T1-weighted, and fat-suppressed images is most useful for interpretation. T1-weighted

Fig. 21-3 • Sagittal magnetic resonance image of the distal aspect of a limb using a T1-weighted spoiled gradient echo sequence. The high signal intensity in the medullary cavity of the phalanges and navicular bone is caused by fat. No signal appears in the deep digital flexor tendon, straight sesamoidean ligament, and cortical bone. Higher signal intensity in the most distal portion of the deep digital flexor tendon is probably a magic angle effect (M). Synovial fluid is dark (low signal intensity) in the navicular bursa (N), distended digital flexor tendon sheath (D), and proximal and distal interphalangeal joints, but cartilage has a relatively higher signal intensity.

Fig. 21-4 • Sagittal magnetic resonance images of the distal aspect of a limb using a T2* gradient echo sequence. **A**, 3D T2* gradient echo image shows a relatively high signal intensity associated with medullary fat of the phalanges and navicular bone, but on this sequence fluid has high signal intensity (compare with Figure 21-3). Synovial fluid in the navicular bursa and joints has high signal intensity, but cartilage has relatively low signal intensity. **B**, Fat-saturated, 3D T2* gradient echo shows the absence of fat signal in the medullary bone and improved contrast between articular cartilage and surrounding structures.

images are often best for evaluation of tissue contours and anatomy, and fat-suppressed techniques are required for evaluation of bone medullary tissues.

In general, fluid (and edema) is hypointense on T1-weighted and hyperintense on T2-weighted images, but increased protein content in fluid also leads to increased signal intensity on T1-weighted images. On T2-weighted images, presence of blood results in a relative decrease in signal intensity compared with edema. Immature granulation tissue has high signal intensity on T2-weighted images, whereas mature fibrotic tissue has a low intensity on T2-weighted images.

Bone

Although cortical bone has low signal intensity, MRI is extremely useful for detecting bone pathology. Alterations in periosteal or endosteal surface contour may indicate bone disruption, osteophytes, or enthesophyte formation (Figure 21-5). Appearance of adjacent tissues should also be evaluated (Figure 21-6). Trabecular architecture can be seen using MRI, and alterations can be monitored. Bone pathology is frequently detected as an increase in signal intensity in T2-weighted and fat-suppressed images and a decrease in signal intensity in T1-weighted images and may represent bone necrosis, inflammation, trabecular microdamage, hemorrhage, fibrosis, and bone edema (Figure 21-7). Very small focal lesions in the cortical or subchondral bone may be associated with large areas of signal abnormality in the local cancellous bone. Residual changes on MR images may be present for months after clinical recovery. Bone abnormality may also be reflected by increased bone density (mineralization, sclerosis), seen as low signal intensity on both T1- and T2-weighted images.

Fig. 21-5 • A sagittal T2* gradient echo magnetic resonance image of a carpus demonstrating osteophyte formation on the distal aspect of the radius and the proximal aspect of the radial carpal bone in the antebrachio-carpal joint (arrows). There is synovial effusion of the antebrachio-carpal and middle carpal joints with synovial proliferation on the dorsal aspect of the antebrachio-carpal joint.

Tendon

Like cortical bone, tendons and ligaments generally have low signal intensity on both T1- and T2-weighted images, thus appearing nearly black except where muscle tissue is present. Increased signal intensity indicates tendon or ligament damage. In acute stages, with inflammatory change, or tissue necrosis, damage is detected as swelling and increased signal intensity on T1- and T2-weighted images (Figure 21-8). At later stages of healing and fibrosis, the lower inflammatory fluid component results in lower signal

Fig. 21-6 • A transverse 3D T2* gradient echo magnetic resonance image of the distal aspect of a limb showing a comminuted fracture of the navicular bone and fracture of the middle phalanx that had been detected radiologically (F) and laceration of the medial branch of the deep digital flexor tendon (D), which is interposed between the fracture fragments of the navicular bone.

Fig. 21-7 • Sagittal fat-saturated, T2* gradient echo magnetic resonance image of a metacarpophalangeal joint showing an area of high signal intensity in the subchondral bone of the proximal phalanx (arrow), representing a pathological condition of the bone. Histopathological examination revealed subchondral bone edema, inflammation, and trabecular microdamage.

Fig. 21-8 • A transverse 3D T2* gradient echo magnetic resonance image of the distal limb of a horse with lameness that was alleviated by intrathecal analgesia of the navicular bursa. There is an area of increased signal intensity within the medial branch of the deep digital flexor tendon (*D*), with adjacent granulation tissue protruding into the navicular bursa.

intensity on T2-weighted images, but signal intensity on T1-weighted images remains higher than that of normal tendon. Changes to the peritendonous tissues should also be considered.

Ligament

Mild ligament damage can be detected by the presence of periligamentar signal alteration (increased on T2-weighted images), intraligamentar increase in signal intensity (either focal or diffuse), and ligament enlargement ([Figure 21-9](#)). Tears can be represented by thinning or discontinuity. There may be evidence of damage at the ligament origin or insertion. Damage to the bone at the origin or insertion of the ligament may be seen as increased signal intensity on fat-suppressed or T2-weighted images and with decreased signal intensity on T1-weighted images. Enthesophyte formation, endosteal reaction, or osseous cystlike lesions at the origin or insertion of a ligament may also reflect ligament abnormality.

Articular Cartilage

Cartilage damage can be seen directly using MR images as changes in signal intensity and/or alterations in contour. Use of fat-suppressed images not only improves contrast in the cartilage itself but also highlights subtle areas of increased signal intensity in the subchondral bone, which may draw attention to a defect in the overlying articular surface. Likewise, focal alteration in the endosteal contour of the subchondral bone in T1- and T2-weighted images may also highlight a region of cartilage pathology.

Synovial Fluid, Synovium, and Joint Capsule

Displacement of the capsular margin represents synovial distention, and damage to the capsular tissues may be seen as thickening or discontinuity of the margin. Using

Fig. 21-9 • A sagittal T2* gradient echo magnetic resonance image of the fetlock of a horse with lameness that was alleviated by intraarticular analgesia of the metacarpophalangeal joint. There is a linear area of high signal intensity in the straight sesamoidean ligament (*white arrow*). Increased signal intensity within the superficial digital flexor tendon (*black arrow*) corresponds to an area of cartilage metaplasia.

Fig. 21-10 • Transverse T2* gradient echo magnetic resonance images at the level of the musculotendinous junction of the superficial digital flexor tendon of the left (*shown on the left*) and right forelimbs. There is enlargement of the left superficial digital flexor tendon and its accessory ligament. Normal muscle tissue (*areas of high signal intensity*) is replaced by an area of low signal intensity consistent with scar tissue (*arrow*).

MRI, it is possible to differentiate acute from chronic synovial hyperplasia and to determine the chronicity in hemarthrosis.

Muscles

Muscular inflammation appears as increased signal intensity on T2-weighted images, whereas lower signal intensity on T2-weighted images may represent fibrosis ([Figure 21-10](#)).

ARTIFACTS

As with any imaging technique, MRI is prone to artifacts that may confuse the interpreter. Ghosting (repeated

picturing of a structure throughout the image) originates from movement during the acquisition of data. This can cause problems in anesthetized horses because respiratory chest movement causes large displacements of the upper forelimb during imaging. Ghosting can also occur if there is sway in a standing horse. Motion can be minimized in an anesthetized horse by weighting the limb with sand bags or reducing respiratory excursion by avoiding mechanical ventilation. In a standing horse, use of motion correction techniques has made it possible to obtain good quality images of the distal aspect of the limb even in the presence of some degree of sway. However, to minimize movement, the level and type of sedation are important, and padding or stabilizing the limb may be helpful, as well as supporting the horse's head. Acquisition of high-quality images of the carpal and tarsal regions in a standing horse presents more of a challenge because sway is magnified compared with the relatively static foot.

Anything that disturbs the homogeneity of the magnetic field can severely distort the image, resulting in a magnetic susceptibility artifact. These artifacts are more prominent in gradient echo sequences and are particularly induced by the presence of metal. Therefore shoes and residual nails must be removed from feet, and dirt must be cleaned from the sulci of the frog. Chemical shift artifact occurs when fat and water that are adjacent in the horse are shown farther apart on the image. If part of the horse is just outside the field of view but produces a signal detectable by the receiver coil, this may be shown incorrectly within the field of view, known as aliasing. The Gibbs effect (truncation artifact) results from undersampling of data and occurs when bright or dark lines appear parallel and adjacent to borders of abrupt intensity change. For example, a line of low signal intensity is incorrectly shown running through a high signal intensity area.

Partial volume effects result when structures passing obliquely through the slice of tissue are imaged; these are important when either the shape or signal intensity of

tissues is assessed. Reducing the slice thickness and improving resolution minimize this effect.

The magic angle effect appears when collagen fibers are located at an angle of approximately 55 degrees to the static magnetic field. This is most important in ligaments and tendons, although it has been reported to occur in cartilage and results in an artifactual increase in signal intensity, which may mimic injury. Structures that are most likely to be affected depend on the direction of the magnetic field. In high-field-strength magnets where the magnetic field is parallel to the long axis of the limb, the magic angle effect is most likely at the insertion of the deep digital flexor tendon. However, in low-field-strength magnets with the magnetic field perpendicular to the long axis of the limb, there is more likelihood of a magic angle effect in the collateral ligaments of the distal interphalangeal joint and the oblique distal sesamoidean ligaments.^{8,9} The magic angle effect is less evident on T2-weighted compared with T1-weighted images. Increasing the TE as in fast spin-echo sequences reduces the magic angle effect.

INDICATIONS FOR MRI IN EQUINE LAMENESS

MRI is most useful when pain causing lameness has been localized to a region of the limb but where a definitive diagnosis has not been made with other diagnostic imaging techniques. If abnormalities have been identified, these may be insufficient to explain the degree of lameness or a more accurate prognosis may be required; thus MRI may be justified. In a horse with foot pain with a suspected penetrating injury MRI may be chosen instead of radiography.

MRI can be invaluable for diagnosis and monitoring of orthopedic conditions in the equine limb. However, it is important that an interpreter is aware of the limitations of MRI to avoid overinterpretation or misinterpretation of signal intensity changes observed on MR images. Therefore findings should be interpreted in light of clinical findings and other diagnostic information.

Chapter 22

Gait Analysis for the Quantification of Lameness

Kevin G. Keegan

Evaluation of lameness in horses is a skill first learned by training and then sharpened with experience over time. The standard of practice is an initial subjective evaluation of the horse while moving to detect and then localize the source of pain causing lameness to the affected limb or limbs. It is a difficult endeavor in horses with mild

lameness, when only subtle changes in movement from normal are present. There is substantial disagreement, even between experienced clinicians, in the identification and localization of the lame limb(s) in horses with mild lameness.¹⁻³ There is also disagreement between experts in the amount of improvement in lameness after nerve blocks,⁴ and equine veterinarians, because they are human, have been shown to be biased. The amount of disagreement between veterinarians on the results of subjective evaluation of lameness in horses is what would be expected for any difficult diagnostic test.

A contributing source of disagreement is the limited sensitivity of the human eye, which has an estimated time resolution of about 10 to 15 samples per second.^{5,6} Events in stride of a horse trotting at 4 meters per second, which is about 1.5 strides per second, occur at a frequency of twice the stride rate, or about 3 times per second.⁷ To prevent significant errors in detection of signal amplitude, the sampling frequency should be, at a minimum, 5 times the frequency of the event being detected.⁸ Therefore the

natural capability of the human eye is below or just at the minimum required to detect important asymmetry in motion events used to judge lameness in horses. All the objective methods of lameness evaluation discussed in this chapter sample data at frequencies higher than that of the naked eye, and thus are theoretically capable of higher accuracy. An objective, precise, and accurate method of lameness detection and quantification in horses is certainly justifiable.

The purpose of this chapter is to introduce and summarize the gait analysis methodology currently being studied or used. Emphasis is given to those that could be used by private practitioners. To be effective, any such system has to be easy to use, and data collection and analysis must be quick. It must be affordable and capable of providing the veterinarian with adequate return on investment. It may be most useful to veterinarians as an aid in detecting and evaluating horses with subtle lameness and lameness in several limbs. Natural stride-to-stride variability must be overcome, so that small differences in subtle lameness can be detected. For example, to detect subtle differences after diagnostic analgesia or after treatment, any such system must be capable of collecting data from multiple contiguous strides. Lameness over ground may be different from lameness on a treadmill; therefore any system must be capable of collecting data when the horse is moving over ground. Also, ideally, any system should be capable of detecting and evaluating lameness in all limbs simultaneously.

There are two general approaches to using gait analysis to detect and measure lameness in horses: kinetics and kinematics. A kinetic technique measures ground reaction forces. A kinematic technique measures motion of the body. There are advantages and disadvantages for each general approach.

KINETICS

Kinetics can rightly be considered a more direct method (compared with kinematics) for detecting and measuring lameness in horses. If a horse has pain during the weight-bearing portion of the stride because of lameness, it bears less weight on that limb, resulting in lower peak vertical ground reaction forces (GRFs) on that limb. Certain lameness conditions may decrease horizontal or transverse GRFs, but the effect on the vertical GRFs is usually most prominent.

Kinetic methods to measure GRFs include a stationary force plate, pressure-measuring pads, instrumented horse shoes, and force-measuring treadmills. A stationary force plate is the most commonly used and cited method, but each method is briefly discussed. A stationary force plate, because of its widespread use in lameness research centers around the world, is discussed in more detail.

Pressure-measuring pads are force or pressure distribution measurement systems consisting of force sensor elements installed between matting surfaces. A horse is led over the pressure-sensitive pad to collect data from single or, if the pad is long enough, a few consecutive strides. Pressure-sensitive pads can be cut and customized to fit the bottom of a horse's foot and then placed between the bottom of the foot and a shoe in an attempt to collect data from multiple contiguous strides.^{9,10} This technology is

ideal for mapping the force or pressure profile of a surface, but peak force or pressure can also be quantified. With further development and marketing this technology may become useful for routine evaluation of shoeing techniques designed to alter force distribution within the foot. Currently there are only a few equine practices in the United States using this technology clinically to evaluate lame horses.

Instrumented horse shoes are custom-built systems designed to either directly, with force transducers, or indirectly, with strain gauges, measure vertical GRFs to the hoof during weight bearing.¹¹⁻¹⁴ Their main advantage is the ability to collect data from multiple contiguous strides in an overground, field-like setting. The main difficulties and disadvantages of instrumented horse shoes include the complexity, size, and weight of the instrumentation, which affect normal hoof and limb movement and gait. Although there are several recent reports of force-measuring horse shoes used successfully in research investigations, currently there are no commercially available systems for a practicing veterinarian to use. Strain gauges glued to the hoof wall, with the resulting strain to the hoof during weight bearing estimating GRF, can act as a surrogate for an instrumented horse shoe. Disadvantages of any hoof-mounted system for measuring GRFs to detect lameness include the need to instrument all four feet simultaneously and, more importantly, the extreme dependence of results on surface characteristics. Because of these disadvantages and the technical and design expertise required for development, it is unlikely that such a device will quickly become adopted for use during routine lameness evaluations.

A force-measuring equine treadmill is a unique piece of equipment consisting of piezoelectric load-sensitive sensors in a treadmill platform (Figure 22-1).^{15,16} The only working system in regular use is at the University of Zurich in Switzerland. The force-measuring equine treadmill is exceptional for detecting small changes in lameness between treatments because of its ability to collect data from multiple, contiguous strides. It is also exceptional for determining severity and location of compensatory lameness because it is capable of measuring vertical GRFs in all four limbs simultaneously.¹⁷ It is a one-of-a-kind, custom-built, installed piece of equipment, and as such is unlikely to be adopted for use as a lameness diagnostic aid in any but the most sophisticated equine private practices or research centers.

A stationary force plate is the most widely used and available kinetic technique for objective evaluation of lameness in horses.^{18,19} Under controlled conditions of constant speed the coefficient of variation of vertical GRF between strides in both lame and sound horses is remarkably low.²⁰⁻²² Thus a lesser number of stride repetitions are required to achieve repeatable results, and small differences between treatments can be detected. A stationary force plate is also sensitive to subtle lameness detection, with some studies suggesting that force plate detection of lameness (decreased vertical GRF) is more sensitive than the human eye in subjective evaluation of lameness.^{23,24} A stationary force plate, unlike the aforementioned other kinetic techniques, is also capable of measuring horizontal GRFs, which may be helpful in further differentiating type of lameness, that is, acceleratory or deceleratory. There are several force plates worldwide that are used, at least

Fig. 22-1 • Treadmill-integrated force-measuring system capable of determining the vertical ground reaction forces and the hoof positions during stance phase of all limbs simultaneously. F_z , vertical ground reaction force in kilonewtons. 1, Traction belt; 2, shock absorber; 3, treadmill platform; 4, treadmill frame. R1 through R9, piezoelectric force sensors of the right side of the treadmill. (Drawing courtesy Dr. Michael Weishaupt, University of Zurich, Switzerland.)

occasionally, for evaluation of lame horses. Despite the high accuracy and precision of a stationary force plate, most experts agree that five or six strikes on the force plate are needed for acceptable results.^{10,20-22} Because a horse does not always strike the force plate on every attempt, the process is time consuming. Also, the size of commercially available force plates is too small, such that data from only one hoof (occasionally two hooves) are collected at one time. Collection of data from contiguous strides and simultaneous measurement of all four limbs to detect and evaluate compensatory or secondary lameness is not possible. Therefore a stationary force plate has not been readily accepted as a tool for routine, clinical evaluation of lameness.

KINEMATICS

Using kinematics is an indirect method of detecting and quantifying lameness. Pain of lameness causes the horse to bear less weight on the affected limb. The decreased vertical GRF during weight bearing perturbs, in some way, the normal, expected motion of the torso, head, neck, and limbs, usually by increasing asymmetry of movement between the right and left strides. However, motion of the torso, head, neck, and limbs is perturbed by causes other than lameness as well; for example, conscious movement of the head in a curious or anxious horse. Thus in lame horses motion perturbation is more variable than change in GRF. Therefore kinematic techniques must be able to collect numerous (more than is required for a stationary force plate), contiguous strides to attain the sensitivity required to detect and evaluate mild to moderate lameness. However, because most veterinarians observe changes in motion in a horse's gait during their subjective evaluation, kinematic techniques generate results that are generally more intuitive and well understood. Important findings in kinematic studies can be easily applied by a practicing veterinarian in a standard lameness evaluation.

Until only very recently the most commonly used kinematic technique consisted of filming the horse in motion

with cameras and then analyzing the collected motion with software on a remote station. The horse is not instrumented except for possibly attaching lightweight reflective markers for easier identification of the body parts of interest. There are many different commercially available, camera-based systems for kinematic evaluation of lameness in horses. These systems use different types of cameras with different capabilities and various, custom-designed software packages with varying capabilities for data analysis. They all depend on unobstructed, line-of-sight light transmission.

I have used camera-based kinematic gait analysis to study and evaluate lameness in horses since the early 1990s and have come to the following conclusions.^{1,25-38} Camera-based techniques are reliable, accurate, and sensitive for detecting and evaluating lameness if two conditions are met: (1) multiple, contiguous strides must be collected to overcome the natural stride-by-stride variability, so that small differences can be detected; and (2) the size of the field of view compared with the size of the subject must be controlled and kept as small as possible for constant and precise spatial resolution. These limitations can be relaxed somewhat for lameness in the moderate to severe range but are absolutely vital for detection and evaluation of mild lameness. Essentially these limitations confine the use of this technique for evaluation of lameness to a treadmill. Adequate data can be acquired with the horse moving over ground in front of the camera, but to capture the movement from enough strides with reasonable spatial resolution, multiple passes are required. Because of these limitations it is unlikely that camera-based kinematic gait analysis technique can be used in clinical practice. However, it is a useful investigative tool, and there are many camera-based kinematic studies of lameness from which practical information for an equine practitioner can be extracted.^{1,25-80}

The long list of motion parameters that may have some association with lameness posed a problem in early studies attempting to develop objective kinematic techniques. There was always the question of what parameters were best at differentiating a sound from a lame horse? Many

investigators used a shotgun approach, measuring many different variables, on small numbers of horses, calculated from a relatively small number of contiguous strides. Under these conditions, moderately severe lameness was necessary to find significant differences between sound and lame horses or between lameness grades. Results were frequently conflicting, with studies using different models of induced lameness finding different motion parameters as the most sensitive for lameness detection and quantification. Most kinematic studies of lameness involve evaluations of horses trotting on a treadmill, where assumptions about torso acceleration and deceleration or the biomechanics of limb impact and push-off are not the same as in the natural overground state. Despite these limitations, there are numerous motion parameters that have been shown to be useful for detecting and quantifying lameness in horses.

In horses with unilateral lameness, fetlock extension and distal interphalangeal joint flexion are less during weight bearing of the lame limb compared with the sound contralateral limb.* This is true for both forelimb and hindlimb lameness. These kinematic measures are considered to be two of the most sensitive indicators of weight-bearing lameness. Fetlock extension during the lame limb stance phase was 8 degrees less than in the nonlame limb stance phase in a sole pressure model of induced grade 1 (of 5) lameness.⁷⁶ However, whether 8 degrees of difference in fetlock extension can be detected by the unaided human eye in a horse at a trot is a matter of conjecture. Carpal extension during stance is reduced, but only in horses with moderate to severe lameness.^{27,56,76} Proximal limb joints become more flexed during weight bearing of the lame limb, resulting in an overall limb shortening during stance,^{47,76} a compensatory mechanism to reduce peak vertical GRF. Because of the competing opposite mechanisms of increased proximal joint flexion and decreased fetlock extension during lame limb stance, overall limb shortening during lame limb stance is probably not a very sensitive indicator of lameness.

In weight-bearing lameness of mild to moderate intensity, stance duration of the lame limb is increased compared with the sound limb.^{16,17,25-27,81} This may seem counterintuitive but is an effective method to reduce peak vertical GRF by spreading the entire vertical GRF impulse over a longer time. The difference between lame and sound limbs is small at the trot even when lameness is of moderate intensity.^{27,43,82} It is unlikely to be seen by an unaided human eye but can be measured by expanding the time domain with slow motion review of high sampling-rate video. Length of forelimb retraction, or the extent to which the horse will keep the forelimb on the ground between full weight bearing at midstance and end of breakover, has also been reported to change with forelimb lameness.^{27,48,76} In a sole pressure-induced lameness model, forelimb retraction was shortened in the lame forelimb at the walk.²⁷ Sound forelimb retraction has also been reported to be reduced in forelimb lameness.⁷⁶ Results reported for the association of forelimb retraction with lameness are not clear enough for forelimb retraction to be considered a sensitive indicator of forelimb lameness.

The length and shape of the limb flight arc during the swing phase of the stride are commonly perceived to be

associated with both forelimb and hindlimb lameness. Forelimb protraction, or the extent to which the horse swings the limb forward before impact, has been reported to increase or decrease with lameness, depending on the location of pain within the limb.^{27,57,76} Heel pressure-induced forelimb lameness, similar to navicular disease, causes decreased forelimb protraction, and toe pressure-induced lameness, like laminitis, causes increased forelimb protraction.²⁷ Hindlimb protraction, by contrast, seems to be a sensitive indicator of most causes of weight-bearing hindlimb lameness.^{28,48} It can also be easily appreciated when looking from the side of the horse as it passes by the evaluator. Comparing the space between the retracting forelimb and protracting hindlimb during each half of the stride during the walk and especially the trot is easy to do and can be a highly productive exercise for detecting difficult hindlimb lameness in the horse.

The association of other swing phase parameters with lameness and their sensitivity for detection of lameness are less clear. Stride length of the lame limb is usually less than the sound limb, but significant differences are not seen until lameness severity is of moderate intensity.^{41,43} Step length, or the distance between placement of opposite limbs, is less between placement of the lame and then sound limbs than between placement of the sound and then lame limb.⁷⁶ Height of foot flight arc may be increased or decreased in a lame forelimb compared with the sound forelimb, and the shape may be different, depending on the cause of lameness.^{1,21,48,60} Although it is commonly perceived that horses with hindlimb lameness drag the toe on the affected side because of low hoof flight arc, this is not always the case. In a hindlimb, height of hoof flight arc is determined by two competing factors, with the strongest determining the overall effect. Decreased propulsion during push-off of the lame hindlimb causes the hind torso to rise less. To bring the affected limb forward during the swing phase of the stride without dragging it on the ground, the proximal limb joints flex more. The comparative extents of the decreased torso rise and increased limb flexion determine the height of the hoof flight arc. Anecdotally, limb abduction or adduction during the swing phase of the stride is thought to be helpful for determination of forelimb and hindlimb lameness in horses, and the direction of horizontal swing has been associated with lameness in specific locations; for example, forelimb abduction (swing out) for carpal lameness, hindlimb adduction (swinging in) for distal tarsal lameness, and hindlimb abduction for stifle lameness. The specificity of forelimb or hindlimb abduction to detect and locate lameness has not been studied adequately. In one study of amphotericin-induced carpal lameness, carpal abduction during swing was not increased in the lame limb.⁴³

There is substantial evidence from numerous studies indicating that the most sensitive kinematic measures for detecting lameness in horses are the motion parameters associated with asymmetry of vertical torso movement; more specifically, vertical displacement, velocity, and acceleration of the head and neck for forelimb lameness and of the pelvis for hindlimb lameness.* In sound horses, asymmetry of trunk and proximal limb movement is less than that of the distal limb.⁵¹ In horses with weight-bearing

*References 25, 27, 28, 41, 48, 57, 76.

*References 7, 28, 29, 31, 33, 43, 46, 47, 49, 52, 60, 63.

lameness, asymmetry of trunk and proximal limb movement is greater than that of the distal limb.⁶⁰ Thus if using asymmetry between movement of the right and left sides of the body as the metric for detecting and quantifying lameness, one should concentrate on movement of the torso and put less credence in movement of the limbs. In a directed attempt to determine the best indicators of forelimb lameness, vertical movement of the head provided the best classification between sound and lame limbs than any movement in the forelimbs.³¹ As stated by one prominent equine veterinarian with experience using kinematics to determine lameness in horses, "Load redistribution in lameness is possible only by altered vertical movements of the trunk, head, and neck."⁷⁶

Asymmetric vertical torso movement in forelimb lameness is best expressed in movement of the head and neck.* Asymmetric vertical movement of the head amplifies asymmetric vertical movement of the body's center of mass because of the long moment arm of the neck.^{34,47,76,82,83} In contrast, asymmetric vertical movement of the withers was shown to be less sensitive for detecting forelimb lameness.^{43,84} Asymmetric vertical movement of the head was shown in many studies to be one of the most sensitive kinematic indicators of forelimb lameness.[†] This, of course, is what many equine practitioners see when they evaluate horses for forelimb lameness, and it is routinely known as the "head bob." "Down on sound" and "up on bad" are both used to describe the vertical asymmetric motion of the head in horses with forelimb lameness. Simply put, the head is supposed to move down more and to a lower height when the sound forelimb is in stance, and it is supposed to move up more and to a higher height after push-off of the lame limb. It is not as simple as this because both of these statements are not mutually exclusive. In addition, whether one is interpreting total vertical head excursion or the end maximum or minimum heights of the head during the strides of right and left forelimbs, neither is correct in every horse. Minimum head position was proposed to be most diagnostic of impact forelimb lameness, the most common type of forelimb lameness in the horse, with the head moving down to its lowest position during the stance phase of the sound limb.³⁷ Additionally, maximum head position after push-off of the lame limb when the pain of lameness occurs in the second half of stance (lameness likely of lower incidence in the forelimb) is higher than after push-off of the sound limb.³⁷ This description of head movement associated with forelimb lameness has not been sufficiently proven experimentally and is solely based on hypothetical mathematical modeling of the head and torso acting as free bodies moving in opposite directions during the trot. If this description is true, then a careful study of vertical head motion may give the equine practitioner valuable information for localizing lameness within the affected forelimb.

The best indicators of asymmetric hind torso movement for detection of hindlimb lameness in the horse are (1) differential vertical movements of the tubera coxae, the "pelvic rotation" or "hip hike" technique,^{28,39,84} and (2) asymmetric vertical movement of the entire pelvis between left and right hindlimb stance phases, paralleling the "head

bob" technique for detection of forelimb lameness.* The first method is easier to see in most horses with hindlimb lameness but has been criticized as misleading in the occasional horse with asymmetric pelvic anatomy and insensitive to rapid alleviation of lameness after nerve blocks. The second method, because the overall vertical movement is less, is more difficult to appreciate in horses with mild hindlimb lameness. However, because whole pelvic fall better mimics the association of vertical GRFs, it is probably more sensitive and accurate. The "pelvic rotation" or "hip hike" method centers on the fact that vertical displacement of the lame-side hemipelvis is greater than of the sound-side hemipelvis. The pelvis appears to rotate toward the side of lameness. Easily visible markers fixed to the right and left tubera coxae may help to detect this asymmetric movement. The best position for the evaluator using this method is behind the horse moving away from the evaluator. The vertical displacement method detects the whole pelvis moving down to a lower height during the stance phase of the sound hindlimb or the pelvis moving up to a greater height after push-off of the sound limb. An easily visible marker fixed to the most dorsal aspect of the pelvis between the tubera sacrale may help to detect this asymmetric movement. Using this method the evaluator can be either behind the horse as it moves away or beside the horse as it passes by. Horses with an impact type of lameness, that is, greatest pain in the deceleratory phase of stance, should primarily display asymmetric downward movement in the pelvis. Horses with an impulsive type of lameness, that is, greatest pain in the acceleratory phase of stance, should primarily display asymmetric upward movement of the pelvis.³⁷

Body-mounted inertial sensors are the best for an objective kinematic system of lameness evaluation in horses.^{30,32,84,85} Body movement can be detected from multiple contiguous strides and wirelessly transmitted to a remote hand-held computer in a field situation. To be clinically useful, a body-mounted inertial sensor system must satisfy several criteria, including (1) the inertial sensors must be small and light enough so that normal movement is not affected; (2) data from sensors must be sampled at a rate greater than the sampling rate of the human eye using digital transmission of sufficient bit size for accurate signal representation; (3) range of data transmission should be far enough to allow measurement of movement in the environment normally used by the veterinarian; (4) data collection and analysis should be quick; and (5) the reported measures must be valid for quantification of lameness and easy to understand.

Size of the actual sensing element is not the limiting factor in the end size and weight of the entire apparatus attached to the horse's body. Micromachined accelerometers and gyroscopes are very small. Apparatus size is dictated by the size of commercially available radio components and batteries needed for adequate transmission range and power usage. True, vertical movement, the measure of most importance for lameness detection, requires multiple, simultaneously collected sensing elements (accelerometers, gyroscopes, and magnetometers). The power requirement for transmission, and coincidentally the size and weight or "footprint" of the sensor, increases with increasing number

of sensors sampled. Higher sampling (e.g., 200 Hz over 50 Hz), increased bit size (e.g., 12-bit transmission over 8-bit), and range of transmission (e.g., 100 m vs. 30 m) also increase demands for power usage, which translates into bigger and less ideal body-mounted sensors. Using data-logging equipment attached to the horse to circumvent this size-transmission tradeoff is not convenient for a veterinarian. A veterinarian does not want to instrument the horse, collect data, stop the horse, take equipment off the horse, or download data after data collection, and then do data analysis. The veterinarian wants results quickly while performing the normal lameness evaluation, without watching computer screens or worrying about whether data are being collected properly. The end result or completed analysis should be accomplished, if not in real time, in as little time as possible. The results should be understandable to practicing veterinarians, some of whom may

not have much experience in computers, mathematics, statistics, or biomechanics and who may not have the luxury of spare time to gain such.

At the time of the writing of this chapter there are a few private companies and university laboratories around the world investigating and developing a body-mounted inertial sensor-based kinematic evaluation system for use in horses (Figure 22-2). The remainder of this chapter briefly describes some of these systems.

EquuSys Inc. (Sudbury, Massachusetts, United States) is marketing EquuSense Equine sensor systems for analysis of equine performance, including lameness. EquuSense Equine sensor systems are composed of sensors with multiple sensing units (e.g., accelerometers, gyroscopes, and magnetometers) and telemetry capability (WiFi, GPS, and Bluetooth) that are attached to the horse, and accompanying hardware (a laptop computer) and software. Each sensor

provides objective and accurate information on its position, velocity, acceleration, orientation, and rotation relative to the horse or to a global reference frame. The software can track from 8 to 18 sensors, depending on the product platform selected, at up to 2000 frames/s in real time. The sensors weigh less than 100 g and can be attached to the horse with specially designed boots and pouches. The data are analyzed to give the user a graphical output of sensor trajectories. This system is a more practical, field-ready replacement for the more familiar camera and marker kinematic systems. The user determines what trajectory variables should be measured and how measured values are analyzed.

Lameness Locator is a wireless, body sensor-based lameness evaluation system developed by equine veterinarians and engineers at the University of Missouri in collaboration with engineers at the Hiroshima Institute of Technology in Japan. It is licensed to Equinosis in Columbia, Missouri for further development and commercialization to equine veterinarians only. Lameness Locator consists of three inertial sensors (two accelerometers and one gyroscope) attached to the head, right forelimb, and pelvis. Each sensor is 4 cm by 3 cm by 2 cm in dimensions and weighs less than 30 g. Vertical accelerations of the head and pelvis and angular velocity of the right forelimb are measured and wirelessly transmitted in real time to a handheld tablet computer up to 150 m away. Custom algorithms are then implemented to detect and measure forelimb and hindlimb lameness when the horse trots or walks. The algorithms were developed from previous kinematic research at the University of Missouri using camera and markers attached to sound and lame horses. Best sites for motion detection to measure lameness were determined

using a data-mining approach to analysis of large datasets. Random motion, unassociated with lameness, as a result of a misbehaving or uncooperative horse, which may interfere with detection and quantification of lameness, is extracted from the raw signals. Lameness detection and quantification results are presented to the user in a graphical interface that shows impact and propulsion asymmetry in each stride, with thresholds between what is expected for soundness and lameness. Trend and variability of collected data are also presented. Because forelimb and hindlimb lameness are measured simultaneously, compensatory or multiple-limb lameness patterns can be evaluated. The developers of Lameness Locator claim that it will be most useful to equine veterinarians evaluating horses with mild, subtle, or multiple-limb lameness and in objectively evaluating partial improvements after using diagnostic analgesia. At the time of this writing, Lameness Locator is being field-tested at 25 private practice and university teaching hospital sites in North America and Europe.

Equimetrix is a multidimensional, accelerometer system attached to the girth of an exercising horse. It is marketed by Centaure-Métrieux (Evry, France) primarily in France and the Benelux countries (Belgium, the Netherlands, and Luxembourg). Three-dimensional torso acceleration is collected and logged as the horse exercises. The data are then analyzed, and output is used to measure characteristics of performance, including stride parameters (e.g., regularity, frequency, length, and timing) and “propulsion power.” Although the output of Equimetrix is directed primarily toward assessing performance in exercising horses, existing algorithms could be adapted or new algorithms could be developed to more specifically evaluate lameness in horses.

Chapter 23

Arthroscopic Examination

Mike W. Ross

Arthroscopic surgery is arguably the most important advance in management and one of the most important in diagnosis of equine joint disease. Arthroscopic surgery has been a mainstay in managing joint disease since the early 1980s and has mostly replaced arthrotomy. An effective equine surgeon cannot lack extensive arthroscopic surgical experience, and lameness diagnosticians must understand indications and limitations of the technique. Innovators have used the same instruments for bursoscopy and tenoscopy (see Chapter 24). For a complete description of procedures, instrumentation, and principles of arthroscopy, the reader is referred to *Diagnostic and Surgical Arthroscopy in the Horse*.¹

ADVANTAGES AND DISADVANTAGES OF ARTHROSCOPIC SURGERY COMPARED WITH ARTHROTOMY

Arthroscopic surgery offers several advantages compared with arthrotomy; however, this type of surgery also has some disadvantages. Both are discussed in the following text.

Advantages

Improved Visibility

Improved visibility during arthroscopic examination allows for evaluation of most of the joint compared with the limited view provided by arthrotomy. Even long arthrotomy incisions rarely provide added visibility because overlying capsule, retinaculum, and sheaths make retraction difficult. During arthroscopic examination, cartilage at locations distant to the primary lesion site, synovium, and intraarticular soft tissue structures such as ligaments can be examined. For example, newly described disease conditions involving intercarpal ligaments were not known before arthroscopic examination existed.

Reduced Trauma and Morbidity

Arthroscopic examination is less traumatic and causes less morbidity. Arthroscopic examination allows surgery to be performed through small incisions and requires less surgical exposure and damage to overlying soft tissues, upholding a time-honored principle of limiting trauma. Little pain is observed in horses after arthroscopic surgery compared with arthrotomy, and many horses appear to ambulate normally. However, in an unblinded study of horses after arthroscopy under general anesthesia, horses showed mild but significant increases in discomfort compared with pain-free controls.² Complications such as wound dehiscence and seroma formation are minimal. Horses often show pronounced lameness for several days after arthrotomy. After arthroscopic examination and surgery, owners and trainers expect horses to return to full work soon after surgery, an idea that is fueled by widespread reports of human athletes returning to professional sports quickly after arthroscopic surgery. A general misunderstanding is that incision size is the limiting factor. Although arthrotomy does cause short-lived lameness after surgery, the fear that it will delay onset of training is unfounded because the underlying lesion dictates recovery time. Although not recommended, horses with mild conditions such as osteochondritis dissecans, effusion but no lameness, and those that receive prophylactic arthroscopic surgery can resume training a few weeks after arthroscopic examination or arthroscopic surgery. Arthroscopic surgery can be performed within weeks before a sale, and if hair was not clipped, surgical sites are barely noticeable.

Better Cosmetic Results

Improved cosmesis is a definite advantage. Small incisions cause less fibrous tissue formation, and incisions are difficult to identify 2 to 3 months after surgery. Generally the instrument portal (incision), the site through which the arthroscopic instruments are passed and lavage is performed, suffers more trauma than does the arthroscopic portal, and swelling, reactions, and fibrous tissue production are more common.

Earlier Functional Capability

Earlier return to function was once believed to be an advantage of arthroscopic surgery. However, incision size has little to do with lameness except within the first few weeks after surgery. Lameness observed in horses returned to work 4 to 6 weeks after arthroscopic surgery for substantial articular lesions has nothing to do with incision size. When horses undergoing arthroscopic surgery were given only a brief rest, results were unsatisfactory. Incisions heal from side to side, not end to end, and incision size has no effect on articular healing. Lesions must heal as completely as possible before full work can begin—a process that often takes several months. Type and location of lesions are important because horses with osteochondritis dissecans not involving weight-bearing surfaces can start training within 2 to 3 weeks of surgery, if necessary, whereas those with lesions in critical sites, such as the typical carpal osteochondral fragment, must be given 3 to 4 months of rest.

More Versatility

Improved versatility is a definite advantage because joints considered inaccessible, such as the coxofemoral joint, can

be evaluated. Techniques such as repair of third carpal slab fractures, distal third metatarsal (MtIII) or third metacarpal (McIII) fractures, fractures in other joints, and resurfacing techniques can be done using arthroscopic surgery.

Fewer Complications

Arthroscopic surgery results in fewer complications. Arthrotomy of the scapulohumeral, femorotibial, femoropatellar, cubital, and tarsocrural joints has been associated with dehiscence, seroma formation, and infection, but arthroscopic surgery of these joints is safe.

Disadvantages**Expensive Instrumentation**

Expense of surgical instrumentation is a disadvantage because start-up costs are high, but basic instrumentation is no more costly than routine surgical instruments. Although arthroscopic surgery can be done without video equipment, video arthroscopy is valuable for archiving images. It is much more comfortable than direct-view arthroscopy (looking directly through the eyepiece) because surgery is performed using a comfortably positioned monitor. It allows the procedure to be viewed by others and is valuable in maintaining aseptic technique because breaks in technique often occur during direct-view arthroscopic surgery.

Lack of Surgical Experience

Experience necessary to learn arthroscopic surgery is a disadvantage. Arthroscopic surgery requires skill in stereotactic techniques and orienting and operating without looking at the surgical site, and surgeons must be able to use instruments properly and safely while looking at a monitor. Preoperative planning must be done to ensure that the horse is positioned properly on the operating table and the surgeon has ready access for triangulation. Poor technique may result in iatrogenic damage or extravasation of large amounts of lavage fluid that can severely compromise distention of the joint capsule and thus ability to see adequately within the joint. Experience cannot be gained by simply attending a weekend course but rather by working long hours with cadaver specimens and observing experienced surgeons. Initially arthroscopic surgery can be time consuming until experience is gained, but with experience arthroscopic surgery is faster than arthrotomy.

Equipment Problems

Equipment failures can be a disadvantage, and because arthroscopic examination depends on electricity, a generator should always be available. Instruments are not made to withstand forces applied to cut, grasp, and debride equine bone and, along with the arthroscope, may break.

Improper Case Selection

Case selection is the most important disadvantage. Poor case selection can make arthroscopic surgery difficult and disappointing. Although much information can be gained by arthroscopic examination of any joint, prognosis should be carefully considered when operating on joints in which extensive osteoarthritis exists. Inadequate communication before surgery may leave owners and trainers with too high expectations of results. Often they have little appreciation

Fig. 23-1 • A, Dorsal 25° proximal medial-plantarodistal lateral oblique digital radiographic image of the right hind (RH) metatarsophalangeal joint (MTPJ) in a 2-year-old Standardbred (STB) trotter showing a typical intraarticular located plantar process fragment (*arrow*) easily removed using arthroscopic techniques. This “down angled” oblique radiographic image is useful to evaluate the region between the base of the medial proximal sesamoid bone and the proximal aspect of the proximal phalanx to see these fragments. **B**, Dorsolateral-plantaromedial oblique digital radiographic image of the RH MTPJ in a 2-year-old STB pacing filly with large nonarticular (*large arrow*) and small articular (*small arrow*) plantar process fragments, which were all removed using arthroscopic techniques. To remove fragments outside the joint, a combination of sharp and blunt dissection and use of a synovial resector are necessary.

for the magnitude of cartilage damage and osteoarthritis (OA), and they only see or hear about the chip fracture(s) visible radiologically. Owners and trainers tend to want to do something, but removal of osteochondral fragments from a carpus or fetlock joint with hopeless OA can be time consuming, cause instrument failures, and, worse, often results in a poor outcome. Poor prognosis associated with some conditions must be well communicated to owners before surgery. For example, we recently reviewed the results of surgical and conservative management of scapulohumeral osteochondrosis and found that overall, prognosis was poor.³ Prognosis varied inversely with the severity of radiological changes, and only 15% of potential racehorses started a race. Four of six nonracehorses were sound for intended use. Surgery did not improve prognosis.³

The fragment size that can be easily removed during arthroscopic surgery is limited, and the instrument portal must be enlarged to accommodate such fragments unless ostectomy is performed. The fragment must be located in the joint or at least close to it, a decision that must be made before surgery because arthroscopic surgery is of little benefit if the fragment is not in the joint or close enough to make the approach reasonable and safe. In the metatarsophalangeal joint, large plantar process fragments from the proximal phalanx are often located extraarticularly, and although they may still be best removed using conventional surgical techniques, I have removed large fragments with arthroscopic instrumentation; surgery is facilitated by use of a motorized synovial resector (Figure 23-1). Differentiation should be made preoperatively between fragments free in a joint, which are accessible to surgical removal, and those embedded in the joint capsule and therefore not readily removed. In the stifle joint,

fragments in the distal aspect of the femoropatellar joint may appear radiologically as if they are in the femorotibial joint. Rare fragments in the caudal pouches of the medial and lateral femorotibial joints can be difficult to retrieve, especially if the precise location cannot be determined radiologically before surgery. The approaches to the difficult caudal pouches of the medial and lateral femorotibial joints were recently refined.⁴ Highly mobile fragments in a large joint such as the femoropatellar joint can prove challenging to locate. There is still a limited role for arthrotomy in equine surgery. For example, I still prefer to use a small, medial, middle carpal arthrotomy to repair sagittal slab fractures of the third carpal bone (C3) because I believe I can more accurately place the screw in the medial aspect of the C3, between the C3 and the second carpal bone.⁵ Others prefer a technique using arthroscopic guidance.¹

PRINCIPLES, INSTRUMENTATION, AND TECHNIQUE

Surgical technique, basic and advanced instrumentation, and approaches are well described elsewhere,¹ and in-depth discussion is beyond the scope of this textbook. The basic principle of arthroscopic surgery is to use a rigid 4-mm endoscope to evaluate and perform intraarticular surgery through small incisions. Smaller endoscopes (2.9 mm and smaller) facilitate surgery in smaller joints or to view lesions between joint surfaces. Limited arthroscopic surgery was previously performed through a single incision, and instruments were passed through a second slot in the arthroscopic cannula. Versatility was severely compromised. Triangulation, a versatile technique in use today, uses two distant

portals so that the arthroscope and instruments create two sides of a triangle. For example, during routine tarsocrural arthroscopy the arthroscopic portal is dorsomedial and the instrument portal is dorsolateral. This allows the tips of the instruments to be in the surgical field from distant points and obviates the need for the arthroscope to be close to the lesion. The end of the arthroscope is angled 25 to 30 degrees, and a different view is obtained by simply rotating it. Endoscopes with angles of 70 and 120 degrees can be used to obtain different views and are useful when triangulation is done with incisions close together. The image must be positioned on the screen to optimize special orientation and facilitate stereotaxis.

Arthroscopic surgery can be performed with basic instruments, the most important of which are rongeurs (Ferris-Smith), grasping forceps, bone curettes, lavage cannulae, intraarticular blades, and probes. Arthroscopic surgery depends on the availability of a suitable light source and monitor, digital camera, and recording devices. A fluid delivery system is mandatory, and pumps or other methods to pressurize fluid are preferred to gravity flow systems. Many common lesions removed by arthroscopic surgery are located on the joint margin, and visibility often is compromised when joint capsule and synovium collapse or when bleeding is excessive. Carbon dioxide insufflation is sometimes used and is preferred by some surgeons.⁶ Carbon dioxide insufflation was effective at maintaining distention of the metacarpophalangeal and metatarsophalangeal joints and gave excellent visibility of lesions, but fluid lavage was necessary when bleeding precluded optimal visibility.⁷ Lasers are used rarely. Controlled ablation (coblation), using a form of radiofrequency energy to dissolve tissue, is used intraarticularly and in tendon sheaths and bursae (see Chapter 24). Using a new radiofrequency prototype probe, researchers were able to control cartilage cell death significantly better compared with manual debridement and use of a commercially available probe.⁸ Motorized equipment is useful but expensive. Abrasion arthroplasty units include various motorized burrs to remove and smooth cartilage and bone surfaces and are used in horses with large lesions such as osteochondritis dissecans lesions of the lateral trochlear ridge of the femur. Synovial resectors are alternating, motorized, rotating blades that are helpful in removing synovium and fibrous tissue and are particularly valuable for removal of osteochondral fragments from the dorsal aspect of the distal interphalangeal joint, apical proximal sesamoid fracture fragments, large abaxial fragments originating from the proximal aspect of the proximal phalanx, and fragments from the lateral malleolus of the distal aspect of the tibia, as well as when synovectomy is indicated.

The division between diagnostic and surgical arthroscopy is now artificial because the same instruments are used for both. Diagnostic arthroscopy, that is, arthroscopic examination, generally refers to evaluating cartilage, bone, and soft tissues to gain information for diagnosis and prognosis. The client must be warned that although valuable information is always learned, arthroscopic examination may provide little therapeutic benefit. However, I believe a tendency exists to undersell arthroscopic examination because a positive intervention cannot be made unless the joint is evaluated, and much can be learned about lesions with early arthroscopic examination. This is particularly

true in the stifle, carpus and fetlock joints. Arthroscopic examination is indicated in horses with lameness localized to a joint, but in which radiological findings are negative or equivocal. Scintigraphic evidence of subchondral bone injury is common in these horses, and defects, if present, in overlying articular cartilage can be debrided and attempts at resurfacing performed arthroscopically. In young racehorses with early subchondral bone injury, arthroscopic evaluation usually reveals little to no overlying cartilage damage in those portions of the joint visible from conventional arthroscopic approaches (Figure 23-2). In these horses lack of cartilage damage likely explains the lack of obvious clinical signs such as effusion. Management of horses with novel surgical techniques such as subchondral forage or using drugs targeting subchondral bone modeling/remodeling in combination with rest is recommended.

Fig. 23-2 • A, Delayed-phase scintigraphic images of a 3-year-old Thoroughbred colt with subchondral bone pain localized to the lateral aspect of the left metatarsophalangeal joint using lateral plantar metatarsal analgesia. Focal increased radiopharmaceutical uptake of the distal, lateral condyle of the third metatarsal bone (MtIII) (arrows) can be seen. Radiographs revealed sclerosis but no radiolucency. **B**, Intraoperative view of the plantar aspect of the left hind fetlock joint (dorsal is to the left and medial is uppermost) from an arthroscopic portal in the proximal, lateral plantar pouch showing normal-appearing articular cartilage of the lateral condyle of the MtIII overlying subchondral bone injury as depicted scintigraphically. The proximal phalanx (PI) can be seen just distal to synovial membrane between the PI and the base of the lateral proximal sesamoid bone. The entire articular surface cannot be evaluated, but visible articular cartilage appears normal. A subchondral forage technique (three 3.5-mm holes drilled from the lateral condyle into subchondral bone) was used.

Fig. 23-3 • Intraoperative arthroscopic images of the cranial aspects of the medial femorotibial joint (MFTJ) (**A** [medial is to the left and proximal is uppermost]) and lateral femorotibial joint (LFTJ) (**B** [lateral is to the right and proximal is uppermost]) in a 3-year-old Standardbred gelding with an unusual subchondral bone cyst in the proximal lateral aspect of the tibia (arrows) and enlarged, frayed lateral meniscus (LM). A cranial approach to the femoropatellar joint (FPJ) was used to evaluate the stifle and the septae between the FPJ, and the MFTJ and LFTJ were removed to allow examinations through a single approach. In this horse with left hindlimb lameness, clinical signs of stifle pain were not detected, and the horse was referred for scintigraphic examination, which revealed focal, moderately increased radiopharmaceutical uptake in the proximal, lateral aspect of the tibia. Notice the normal medial meniscus (MM) and articular cartilage of the proximal aspect of the tibia (Tib) in the MFTJ and mild undulation of articular cartilage of the distal femur (Med fem). The subchondral bone cyst and torn edge of the lateral meniscus have been debrided (**B**). Prognosis is guarded at best because of subchondral bone, cartilage, and meniscal injury in the LFTJ.

Scintigraphy and ultrasonography have low sensitivity in the complex stifle joint, and arthroscopic examination should be encouraged. Walmsley et al.,⁹ in a large case series, found that 47% of horses returned to full use, and prognosis was inversely proportional to severity of meniscal tearing, degree of cartilage damage, and radiological abnormalities (Figure 23-3) (see Chapter 46). Arthroscopic examination may uncover proliferative synovitis, intersesamoidean ligament injury, and intercarpal ligament injury. Intercarpal ligament injury often is associated with OA or osteochondral fragments and can cause hemarthrosis and presumably joint instability (Figure 23-4).^{10,11} Lesions in difficult locations can be successfully evaluated and manipulated arthroscopically. Ten of 11 horses that had subchondral bone cysts of the distal phalanx returned to athletic use after arthroscopic debridement.¹² The distal interphalangeal joint can be difficult to evaluate, but a combination of careful manipulation and flexion can improve visibility (Figure 23-5).

Changes in articular cartilage are the most important information gained from arthroscopic examination. Prognosis was found to worsen in proportion to the extent of articular cartilage damage in the carpus,¹³ but all joints are similarly affected. Surface area and depth of damage are important. Widespread damage affecting many cartilaginous surfaces is usually worse than well-defined lesions extending into subchondral bone. Cartilage damage is graded as mild (<20% damage to cartilage and subchondral bone at the primary lesion site), moderate (involvement of apposing bone, but <30% total cartilage and subchondral

bone damage of primary and apposing sites), severe ($\leq 50\%$ of cartilage and subchondral bone damage of primary and apposing sites), and global (extensive cartilage damage visible on most articular surfaces) (Figures 23-6 to 23-8). If cartilage lesions do not extend past the zone of calcified cartilage, healing after surgery will likely be minimal (see Microfracture discussion below).

Occult (not radiologically apparent) osteochondral fragments may be identified by arthroscopic examination. Recognition requires inspection and probing, if necessary, after synovial resection. Common sites include the medial aspect of the intermediate carpal and lateral aspect of the radial carpal bones and small fragments involving the proximodorsal aspect of the proximal phalanx. Unexplained tarsocrural effusion (bog spavin) is commonly caused by osteochondritis dissecans fragments of the distal medial malleolus of the tibia, and although fragments may be suspected radiologically, the presence is confirmed and they are removed arthroscopically. Occult or radiologically suspicious subchondral defects of the third carpal bone, the distal aspect of the medial femoral condyle, and the distal aspect of the MtIII and McIII can be confirmed and debrided.

Most arthroscopic surgery is performed to remove radiologically apparent osteochondral fragment(s). Grading cartilage damage and subchondral bone damage, along with removing one or more osteochondral fragments, is important in assessing prognosis. Discovery of severe cartilage damage in horses with few radiological changes is common, especially in the carpus and fetlock joints. Whenever possible, all aspects of the joint should be evaluated.

Fig. 23-4 • Intraoperative arthroscopic images of the left (**A**) and right (**B**) middle carpal joints (MCJs) showing complete tearing of the medial palmar intercarpal ligaments (*arrows*) in a 2-year-old Thoroughbred filly in race training. The horse was positioned in dorsal recumbency, and distal is uppermost; medial is to the right in **A** and to the left in **B**. The arthroscope has been inserted through a dorsolateral portal between the extensor carpi radialis and common digital extensor tendons in both MCJs. Tearing of the medial palmar intercarpal ligament appears as it courses from the third carpal bone (C3) to the radial carpal bone (RC). The intermediate carpal bone (IC) can be seen. Tearing of the medial palmar intercarpal ligament causes hemarthrosis, a condition previously thought to be idiopathic without arthroscopic examination, and can occur in conjunction with osteochondral fragmentation and associated cartilage damage. When the intercarpal ligament is torn, the palmar aspect of the MCJ can be examined, a finding that is impossible if the ligament is intact.

Fig. 23-5 • Intraoperative arthroscopic images before (**A**) and after debridement (**B**) of the right hind distal interphalangeal joint (DIPJ) in a yearling Standardbred filly with a history of acute lameness and a small wound at the dorsal aspect of the coronary band. Hair was found in the dorsal aspect of the joint and was removed. With the joint in moderate flexion and the joint surfaces retracted using an arthroscopic elevator, this lesion involving the plantar aspect of the articular surface of the distal phalanx (PIII) can be seen (*small arrows*). Notice the articulation between the plantar aspect of the PIII and the navicular bone (*large arrow*). The distal articular surface of the middle phalanx (PII) can be seen.

In racehorses, although cartilage damage and osteochondral fragmentation are often seen dorsally, the palmar/plantar aspect of the metacarpophalangeal joint or metatarsophalangeal joint often has extensive cartilaginous score lines or large, full-thickness areas of cartilage loss on

the medial aspect of the McIII and the medial articular surface of the proximal sesamoid bone (PSB) and on the lateral aspect of the MtIII and the lateral PSB. In nonracehorse sports horses, changes are most prominent dorsally. Lesions of the patella, sometimes with fragmentation,

Fig. 23-6 • Intraoperative arthroscopic images of the dorsomedial aspect of the right metatarsophalangeal joint of a 3-year-old Thoroughbred filly with right hindlimb lameness (dorsal is right, proximal is top). **A**, A small osteochondral fragment (chip fracture, *arrows*) of the dorsomedial aspect of the proximal phalanx (*P-I*) is surrounded by mild cartilage damage. A small partial-thickness “score” line can be seen on the overlying medial condyle of the third metatarsal bone (*MtIII*). **B**, The chip fracture has been removed and surrounding mild cartilage damage debrided. This horse returned to successful racing 6 months after arthroscopic surgery.

Fig. 23-7 • Intraoperative arthroscopic images of the right middle carpal joint of a 3-year-old Standardbred colt (dorsal is to the right and proximal is uppermost). **A**, A small osteochondral fragment (chip fracture, *arrows*) of the third carpal bone (*C3*) can be seen; minimal cartilage damage was found on the radiocarpal bone (*RC*). **B**, The chip fracture has been removed, and surrounding moderate cartilage damage has been debrided. This horse has a good prognosis for racing soundness.

found during arthroscopic examination explain why some horses with large osteochondritis dissecans lesions of the lateral trochlear ridge of the femur perform poorly. Arthroscopic examination is useful in horses with infectious arthritis to evaluate articular surfaces and synovium, identify and remove foreign material (see [Figure 23-5](#)), facilitate removal of fibrin, and perform much more effective and complete lavage than is achieved by through-and-through lavage. Arthroscopic examination usually is reserved for horses with long-standing infections and those

with extensive fibrin accumulation, but the Editors strongly promote its use for acute infection as well. I have not found a good correlation between arthroscopic and ultrasonographic identification of fibrin early in the disease process (the amount of fibrin is overestimated by ultrasonography). Arthroscopic examination can facilitate drain insertion, synovectomy, and debridement or removal of osteochondral defects. Arthroscopic portals can be left open to facilitate drainage after surgery, but this procedure should be used only in horses with refractory infections.

Fig. 23-8 • Intraoperative arthroscopic images of the plantar aspect of the left metatarsophalangeal joint in a 7-year-old Standardbred stallion showing severe cartilage and subchondral bone damage from end-stage osteoarthritis that developed from maladaptive bone remodeling. **A**, A large erosive lesion of the lateral condyle of the third metatarsal bone (*MtIII*) has been debrided (dorsal is to the left and proximal is uppermost). This area is difficult to see, and the arthroscope is positioned between *MtIII* and the lateral proximal sesamoid bone with the joint in as much extension as possible. The proximal, plantar aspect of the proximal phalanx (*P-I*) can be seen. **B**, Severe loss of articular cartilage with exposed subchondral bone (*arrows*) can be seen on the lateral proximal sesamoid bone. **C**, The technique known as microfracture has been performed in the area of complete cartilage loss on the lateral proximal sesamoid bone, but prognosis is hopeless for racing soundness.

SURGICAL PROCEDURES

The specific indications and surgical procedures are discussed in other chapters. Dorsal and palmar/plantar, medial and lateral, and cranial and caudal approaches have been described; the approach, choice of portals, fluid delivery, and instrumentation vary among joints and surgeons. Positioning the horse on the operating table is important to allow access to the involved joint(s), and repositioning may be necessary. Both lateral and dorsal recumbency are used successfully, and choices are based on the surgeon's experience and the number of joints affected. Although standing arthroscopy of the fetlock and

other joints has been described,¹⁴ I prefer to use general anesthesia.

Minimally invasive surgery such as arthroscopic surgery continues to be developed in horses. Standard procedures include fragment removal, debridement and curettage, partial synovectomy, and incision of adhesions. Reduction, fragment removal, and screw placement in horses with condylar fractures of the *McIII* or the *MtIII* can be done using arthroscopic surgery, obviating the need for arthrotomy. A technique to insert one or more cortical bone screws to repair frontal slab fractures of the third carpal bone was an early advance that has led to use of a similar technique to repair radial carpal bone and ulnar carpal

bone slab fractures, PSB fractures, and other unusually located articular fractures.¹⁵ An alternative to arthroscopic debridement of subchondral bone cysts of the medial femoral condyle— injection of the cyst lining with corticosteroids under arthroscopic guidance—appears to give similar clinical results.¹⁶ Thirty-five of 52 horses (67%) were considered successful. Horses with unilateral subchondral bone cysts did better than those with bilateral cysts, and the existence of osteophytes on preoperative radiographs had a negative impact on success.¹⁶

Cartilage Resurfacing

Recently cartilage resurfacing techniques have been used in experimental horses and in a limited number of clinically affected horses. Repair strategy involves creating access to stem cells, growth factors, and blood in subchondral bone to assist in cartilage repair or transplantation (grafting) of tissues, osteochondral grafts, or cells (chondrocytes). Partial- or full-thickness cartilage defects that do not penetrate the subchondral plate heal incompletely or not at all. An important principle in cartilage repair is to curette through the layer of calcified cartilage and perforate the subchondral plate to allow influx of healing elements. Extensive curettage seems to be self-defeating because exposure of large areas of denuded subchondral bone is associated with poor prognosis and often is found in horses with naturally occurring OA. Unfortunately, many defects already involve complete erosion into subchondral bone, at least around and apposing the primary lesion site. A technique known as *microfracture* of the subchondral plate has been introduced and involves using a 45- or 90-degree orthopedic awl (micropick) to create small perforation sites into subchondral bone in the area of cartilage damage.^{17,18} Studies have shown that removal of the calcified cartilage layer alone, or perforation of the layer with the microfracture technique, improves the amount and quality of repair tissue, but this tissue lacks the biomechanical and histological character of hyaline cartilage.¹⁹ The procedure is currently being used, but objective results compared with routine procedures have not been published.

Nixon²⁰ has considerable experience in transplantation resurfacing techniques and is focusing current efforts on using autogenous fibrin laden with insulin-like growth factor-1 and chondrocytes harvested from neonatal foals. An arthroscopic technique using a two-component system was used to implant the graft in experimental and clinically affected horses with defects in the carpus and subchondral cystic lesions of the medial femoral condyle and in the fetlock joint. Early results appeared promising. More recently mesenchymal stem cell grafts improved early healing of full-thickness cartilage lesions; however, there was no significant long-term difference between stem cell-treated and control defects.²¹ In an osteochondral fragment model evaluating articular cartilage and subchondral bone healing and synovitis, injection of either adipose-derived or bone marrow-derived stem cells had similar results to controls.²² It was suggested that the use of stem cells might be beneficial in joints with soft tissue injuries.

A technique called *mosaic arthroplasty* involves using arthroscopic procedures to harvest osteochondral pegs (grafts) from the trochlear groove or the medial border of

the medial trochlear ridge of the femur and implant them in distant recipient sites.²³⁻²⁶ Grafts harvested and implanted using special instruments have better congruence than previously reported osteochondral grafting techniques, most using donor sites in the sternum. Mosaic arthroplasty has been used to manage osteochondral defects and subchondral bone cysts in the medial condyle of the femur, the fetlock joint, and the C3 and was proposed to be useful when conservative management failed.²³⁻²⁶ Seven of 10 horses returned to the previous level of performance after surgery.²⁶ However, in an experimental study the technique was questioned because although there was good incorporation of bony portions of the grafts into recipient subchondral bone, there was substantial cartilage degeneration.²⁴ Large osteochondral flaps (osteochondritis dissecans) in the stifle, tarsocrural, and fetlock joints have been successfully reattached, rather than removed, using polydioxanone pins.²⁷

Postoperative Care

Aftercare instructions differ depending on the joint(s) involved, severity of cartilage damage, surgeon's experience, economic factors, and competition schedules. Bandage and wound care, administration of antiinflammatory, analgesic, and antimicrobial therapy, and suture removal are routine. Decisions about rehabilitation time should be based on the extent of the damage and its location, but often are made based on the perceived need for a quick return to training and performance. Intraarticular therapy with hyaluronan and polysulfated glycosaminoglycans (PSGAG) is often recommended, and although such therapy may be beneficial to reduce inflammatory changes in joints early after surgery, little evidence exists that repair is augmented. I generally recommend intraarticular hyaluronan 14 and 28 days after surgery in horses with mild or moderate cartilage damage and PSGAG, administered intraarticularly 3, 5, and 7 weeks after surgery, for horses with severe or global cartilage damage. Treatment with PSGAG given intramuscularly beginning 2 weeks after surgery (once weekly for 8 weeks) is recommended.

COMPLICATIONS

The infection rate after arthroscopic surgery is low, but not zero, and is generally less than other soft tissue and orthopedic procedures performed in the same hospital. Poor case selection and failure to remove the intended fragments are the most common important complications. Intraoperative radiographs should be obtained if any doubt exists about fragments (number and size) removed. Extravasation of fluid, most commonly at the instrument portal but occasionally at the arthroscopic portal, occurs frequently and is of little concern. Fibrous tissue formation at the instrument portal is common if a large amount of cartilage and bony debris is flushed from the joint or removal of several osteochondral fragments required extensive manipulation. Prolonged drainage from any portal should be managed as potential infectious arthritis. Synovial fistulae occur rarely, but they may require repair. Damage to overlying tendons may cause aesthetically displeasing tenosynovitis that usually responds to injections, but occasionally repair of synoviosynovial fistulae is necessary.

Chapter 24

Tenoscopy and Bursoscopy

Eddy R.J. Cauvin

The advantages of arthroscopy as a diagnostic and therapeutic approach to joints¹ have prompted the development of applications for other synovial cavities (see Chapter 23). *Tenoscopy* is the term used to describe endoscopy of synovial tendon sheaths, usually using a rigid arthroscope.² *Bursoscopy* is used for endoscopy of bursae.

Tenoscopy has many advantages. Traditional approaches to tendon sheaths, requiring long incisions over highly mobile areas, are associated with substantial postoperative risks, including wound dehiscence and ascending sheath infection.³ These techniques are invasive, time consuming, and offer limited visibility of tendovaginal structures.^{2,3} Endoscopic approaches to the carpal tunnel in people have been described^{4,5} and have provided substantial improvements in terms of decreased morbidity, scarring, and loss of function compared with open techniques.^{4,6} Tenoscopy in the horse was first described for the examination of the digital flexor tendon sheath (DFTS).^{1,2} Since the early 1990s, other applications have been described.⁷⁻¹¹

GENERAL PRINCIPLES OF TENOSCOPY AND BURSOSCOPY

Equipment

Standard arthroscopic equipment is used, including arthroscope, sleeve, and obturators; arthroscopic cannulae; probes; grasping forceps; and Ferris-Smith rongeurs. Sharp tenotomes, curettes, and meniscectomy scissors should also be available. A standard 4.0-mm, 25- to 35-degree forward angle arthroscopic endoscope is adequate for most sheaths and bursae, although thinner endoscopes may be useful for extensor sheaths. Light source and video camera apparatuses are as for arthroscopy. Motorized synovial resectors are particularly useful because debridement or synovectomy using hand-operated instruments can be tedious in large tendon sheaths.

Coblation technology (ArthroCare Corporation, Austin, Texas, United States) is a new technology that uses radiofrequency to vaporize soft tissues. I now use radiofrequency probes (Arthrowands, ArthroCare Corporation) to remove proliferative synovial tissue and masses, and a hook radiofrequency blade (Saber 30, ArthroCare Corporation) to carry out annular or retinaculum desmotomy. An added advantage is improved hemostasis.

Surgical Principles and Techniques

The basic principles of arthroscopy are also valid in tendon sheaths and bursae (see Chapter 23). The sheath usually is

distended with fluids to facilitate insertion of the cannula. However, this is not necessary for the carpal and tarsal sheaths, which are not approached through distended pouches.^{9,10} It is generally recommended that the portal be created with a scalpel and the cannula inserted using a blunt, conical obturator to avoid damaging the tendons. A thorough knowledge of the normal endoscopic anatomy of the sheath is paramount for several reasons. First, all the surfaces are covered by synovium and look alike, making identification of the structures difficult. Second, normal anatomical structures such as vinculae and plicae (adhesion-like formations carrying blood vessels to the tendon from the parietal sheath), endotendon (reflection of the synovial membrane, which forms a continuous band attaching the tendon to the sheath along its length), and synovial folds are apparent. These should not be damaged because they participate in the blood supply of tendons within the sheathed portion.¹²⁻¹⁴

Triangulation techniques are applied for instruments using separate portals. These should be created as close as possible to the lesion, although the shape of the sheath often dictates the position of the portals. The longitudinal arrangement of the sheaths and tunnel-like enclosures within retinacula often make triangulation difficult; therefore it may be useful to perform retinaculum desmotomy to improve access to some lesions, or to create instrument portals so that instruments are inserted opposite and toward the endoscope lens.

TENOSCOPY

Tenoscopy of the Digital Flexor Tendon Sheath

The DFTS is the most common site of tenosynovitis. Endoscopy is indicated as a diagnostic procedure to examine lesions of the surfaces of the deep digital flexor tendon (DDFT), superficial digital flexor tendon (SDFT), and parietal surface of the sheath. High-definition ultrasonography allows noninvasive examination of the sheath, its contents, and peripheral tissues, and provides more accurate information about the internal architecture of tendons.¹⁵ However, differentiating some adhesions, tears, and superficial fraying of the tendons may be difficult ultrasonographically.¹⁶⁻¹⁹ Tenoscopy is useful for debridement of masses, such as proliferative (villonodular) synovitis-like lesions and other lesions within the sheath, adhesiolysis, removal of debris, and synovectomy in infectious tenosynovitis.^{2,19,20} A technique for desmotomy of the palmar annular ligament under endoscopic control has been described to avoid inadvertent damage to the tendons, manica flexoria, and other peritendovaginal structures.²¹

The advantages of tenoscopy over traditional open surgery are similar to those recognized for arthroscopy over arthrotomy. They include decreased morbidity and more rapid return to normal function of the sheath and reduced risks of complications, such as wound breakdown, infection, fibrosis, and ankylosis.

Anatomy

The DFTS is organized primarily around the DDFT, which it completely surrounds from the junction between the third and distal quarters of the metacarpal or metatarsal

region to the level of the proximal interphalangeal joint, before tapering dorsally to the DDFT to the proximal border of the distal sesamoid bone.^{12,13,15,22} At the level of the metacarpophalangeal joint, the DFTS also surrounds the SDFT, except for a wide mesotendon over the palmar/plantar aspect of the tendon. At this level the DFTS is bound dorsally by the proximal scutum, a fibrocartilage covering the palmar (plantar) surfaces of the proximal sesamoid bones (PSBs) and intersesamoidean ligament, and palmarly by a tough transverse ligament, the palmar (plantar) annular ligament (PAL), thus forming a nonelastic canal through which both digital flexor tendons run independently. In the pastern region the SDFT separates into two branches and is no longer within the DFTS. The DFTS is bound dorsally by the distal sesamoidean ligaments and palmarly (plantarly) by two broad digital annular ligaments.

The proximal pouch bulges when distended proximal to the PAL and PSBs and contains a number of long villi in normal horses. Several small, subcutaneous pouches appear between the insertions of the PAL and digital annular ligaments abaxially and over the palmar (plantar) aspect of the DDFT in the midpastern region. A number of vascular structures are found, including two large vinculae forming a V-shaped adhesion-like structure between the dorsal surface of the DDFT and the dorsal sheath wall in the proximal pastern. Densely packed villi often are found in that area. The wide palmar mesotendon prevents examination of the palmar aspect of the SDFT in the fetlock region. Immediately proximal to this level, the manica flexoria forms a smooth, thin membrane originating from the axial surfaces of the SDFT and surrounding the DDFT dorsally.

Surgical Technique

The technique for tenoscopic exploration of the DFTS has been described in detail.² The term *palmar* is used in the following description for either palmar or plantar. The horse may be placed in lateral recumbency with the affected limb uppermost for a lateral approach or lowermost for a medial approach. The choice of a lateral or medial portal is dictated by the site of the suspected lesion. However, if no definite lesion has been observed ultrasonographically and if a potential tear is suspected, the horse is best placed in dorsal recumbency with the limb attached to a frame or hoist so that the digit is in slight flexion. This decreases hemorrhage during the procedure. An Esmarch bandage and tourniquet may also be used.

The DFTS is distended with 10 to 20 mL of physiological solution through a needle inserted in the palmar aspect of the midpastern region. Overdistention of the DFTS is avoided because it causes flexion of the digit. A 5-mm longitudinal incision is made through the skin, immediately distal to the PAL, lateral or medial to the DDFT, and 0.5 to 1 cm palmar to the neurovascular bundle, which must be carefully avoided. A stab incision is made into the DFTS, taking care to avoid damaging the DDFT, and the cannula, with a conical obturator inserted in a proximal direction, between the DDFT and dorsal sheath wall (Figure 24-1). The DFTS is lavaged through an 18-gauge needle inserted in the proximal pouch. The obturator is replaced with the endoscope, and examination is carried out from proximal to the level of the portal by rotation and gradual

Fig. 24-1 • Digital sheath tenoscopy. The arthroscope is inserted lateral to the deep digital flexor tendon, immediately distal to the palmar annular ligament.

withdrawal. The proximal pouch is examined, followed by the abaxial aspects of the two tendons. Flexion of the fetlock joint allows insertion of the endoscope between the SDFT and DDFT without damage to the manica flexoria. The endoscope is finally rotated around the SDFT on the side of the portal to inspect the mesotendon. Examination of the opposite side is made possible by flexion of the fetlock and rotation of the arthroscope window palmarly.

The endoscope is then pushed across the DFTS, between the DDFT and dorsal sheath wall, to avoid exiting the DFTS. The endoscope is then redirected distally. The distal part of the DFTS is examined by gradual withdrawal of the endoscope. The vinculae are visible in the proximal pastern region, between the dorsal surface of the DDFT and dorsal wall (Figure 24-2). Palmarly and farther distally, bifurcation of the SDFT branches forms a manica-like ring around the DDFT (Figure 24-3).

Debridement of potential lesions is carried out through separate instrument portals made as close as possible to the lesion to allow for adequate triangulation. At the end of surgery the DFTS is lavaged through a large-bore cannula, and the skin incisions are closed. It is recommended that a pressure bandage be applied for 2 weeks postoperatively. In horses with infection with substantial debris accumulation, it is possible to place a drain, exiting in the distal palmar recess through a separate incision. A drainage portal may also be created in the distal palmar aspect of the DFTS to allow for continuous drainage postoperatively. The incision is then left to heal by contraction and epithelialization.

A technique for transection (desmotomy) of the PAL under endoscopic guidance was described,^{18,20} using a

Fig. 24-2 • Tenoscopic view of the dorsal aspect of the deep digital flexor tendon (DDFT) in the proximal pastern region, showing one of the vinculae (V) between the DDFT and dorsal wall (Sh) of the digital flexor tendon sheath.

Fig. 24-3 • Tenoscopic view of the palmar aspect of the deep digital flexor tendon (DDFT) in the proximal pastern region, showing the manica-like ring (arrow) surrounding the DDFT, between the two superficial digital flexor tendon (SDFT) branches (within the abaxial sheath walls). The dorsal wall (Sh) of the digital flexor tendon sheath is rich in long villi.

desmotomy kit designed for palmar carpal ligament transection in people.^{4,5} This permits adequate examination of the DFTS before PAL transection and prevents inadvertent damage to the tendons and manica flexoria. Although the use of a specific cannula facilitates the procedure, I use a grooved director for the same purpose. A radiofrequency hook blade (Saber 30, ArthroCare Corporation) facilitates the technique because there is minimal hemorrhage and less risk of inadvertent damage to peripheral structures and tendons during insertion and manipulation of the knife.

I have used an alternative technique for digital tenoscopy using an endoscopic portal made proximal to the PAL and dorsolateral to the DDFT. This technique allows adequate examination of the entire DFTS, is useful to examine lesions in the proximal phalangeal region, and provides improved triangulation when surgically treating such lesions. Using a wound as an initial endoscopic portal is often possible, although creating a new endoscope portal and using the wound for instruments is usually preferable after examination is completed.

Postoperative Care

At the end of surgery the DFTS is emptied of fluid and the skin portals are closed with staples or sutures of the surgeon's choice. Damage to the neurovascular bundle by needles and sutures is carefully avoided. The horse recovers with the limb in a pressure bandage from the foot to the distal aspect of the carpus (or tarsus) to prevent DFTS swelling and to reduce motion. Postoperative antibiotics are only necessary in horses with infectious tenosynovitis, but systemic nonsteroidal antiinflammatory drugs (NSAIDs) should be given for several days after surgery. The horse should be restricted to box rest for 3 days, and then it may be walked out in hand to decrease restrictive adhesion formation. Box stall rest with controlled exercise should be continued for 2 weeks until the sutures are removed, and then at the surgeon's discretion exercise is increased progressively. Hyaluronan has been advocated as an adjunctive therapy^{2,17} but should be avoided if infection is present. Passive limb motion with repeated flexion/extension of the fetlock helps reduce stiffness in the initial stages. Cold hosing of the limb is useful to decrease potential swelling and hemorrhage after handwalking.

TARSAL SHEATH

Injuries to the tarsal sheath are relatively common (see Chapter 76). Open surgery has been associated with a high rate of postoperative complications,^{3,10,24} but early results indicate that the morbidity may be greatly reduced with tenoscopy.¹⁰

Anatomy

The tarsal sheath is the sheath of the lateral digital flexor tendon (LDFT), the largest of the two tendons (lateral and medial digital flexor tendons), the fusion of which in the proximal metatarsal region forms the DDFT (see Chapter 76).^{10,22,25} It is paramount to recognize the anatomical location of the plantar nerves and vessels that pass within the plantar flexor retinaculum and the presence of a continuous mesotendon, passing longitudinally along the plantaromedial aspect of the LDFT. However, accidental damage to these structures does not appear to have major consequences.

Surgical Technique

A technique allowing examination of the entire tarsal sheath has been described.¹⁰ Previous distention of the tarsal sheath is not necessary. The medial edge of the sustentaculum tali and medial insertion of the retinaculum are located, and an 8-mm vertical incision is made in the skin and underlying fascia, 8 mm plantar to the edge of the bone at the point where the tendon changes direction

Fig. 24-4 • Tenoscopic views of the tarsal sheath. **A**, Proximal pouch of the tarsal sheath (TS) showing the cranial aspect of the lateral digital flexor tendon (LDFT) and the proximal plantar ligament (PPL) thickening of the plantar capsule of the tarsocrural joint. **B**, Distal recess of the tarsal sheath (TS). At the tarsometatarsal joint, the end of the plantar ligament (PL) is visible. A synovial fold (white arrow) forms a small recess dorsomedially (Re).

over the sustentaculum tali. The absence of blood vessels in the retinaculum deep to the incision is ascertained using hypodermic needles before making a 5-mm stab incision through the retinaculum. Care is taken to avoid damage to the underlying LDFT. The endoscope sleeve and conical, blunt obturator are inserted dorsal to the LDFT in a proximal direction. The obturator is replaced with an endoscope; the tarsal sheath is distended moderately with fluid; and examination is carried out as described for the DFTS by rotation of the window of the arthroscope and gradual withdrawal. After examination of the proximal half of the tarsal sheath, the endoscope is redirected into the distal pouch. The proximal pouch is large and lined by a thin wall (Figure 24-4, A). Muscle fibers from the lateral digital flexor muscle and separate head of the tibialis caudalis muscle may be seen by transillumination through the synovial membrane. Within the tight, rigid canal formed by the sustentaculum tali and retinaculum, the fibrocartilage appears glistening white, and small vessels are seen within the parietal membrane plantarly and in the mesotendon. In the distal half of the tarsal sheath, a fold of synovial membrane forming a small, blind pouch medially is seen dorsomedial to the LDFT at the level of the tarsometatarsal joint (Figure 24-4, B). Distal to this fold, the tarsal sheath continues as a cylindrical, blind recess dorsal to the tendon and contains small villi. The separate sheath of the medial digital flexor tendon is not visible from the tarsal sheath.

If a wound exists, most commonly at the plantaromedial edge of the sustentaculum tali, it may be used as an endoscope portal. Instruments may be inserted as required close to lesions to allow for triangulation. Needles are used to determine the optimal location for the instrument portal.

Carpal Sheath

Tenosynovitis of the carpal flexor tendon sheath (carpal sheath) is relatively rare in horses but can cause severe

lameness associated with carpal canal syndrome (see Chapter 75). Wounds leading to contamination of the carpal sheath are rare but possible. Common causes of non-infectious tenosynovitis include lesions of the SDFT in the carpal region, fractured accessory carpal bone, osteochondromata of the caudal distal aspect of the radius, exostoses of the caudal perimeter of the distal radial physis, and sprain injuries to the carpal sheath,²⁶⁻²⁸ although other causes may exist.²⁹ Effusion may be secondary to lesions outside the carpal sheath, such as desmitis of the accessory ligament of the DDFT (ALDDFT), accessory ligament of the SDFT (ALSDFT), limb edema, and unassociated wounds. Ultrasonography is the technique of choice for investigating carpal sheath distention, but adhesions and subtle fraying of the tendons may not be visible.^{28,30} Radiography is also mandatory to rule out fractures, exostoses, and osteochondromata.^{27-29,31}

Tenoscopy may be useful as a diagnostic tool if lameness is associated with pain localized to the carpal sheath by intrathecal analgesia but where no lesions are visible with other imaging methods. The main indication for tenoscopy of the carpal sheath is debridement and repair of structures within the sheath or transection of the ALSDF.

Anatomy

The anatomy of the carpal sheath has been described elsewhere in detail.^{14,21,30} Briefly, the carpal sheath is organized around the DDFT from the distal caudal aspect of the antebrachium, 4 to 7 cm proximal to the accessory carpal bone, to the metacarpal region. The carpal sheath extends around the DDFT and SDFT in the carpal region, where it is enclosed within a tight canal (the carpal canal) formed by a thick palmar carpal flexor retinaculum palmarly and medially, the accessory carpal bone laterally, and the palmar carpal ligament dorsally. At this level the SDFT is attached palmarly to the sheath wall by a thick mesotendon that contains the median artery and medial palmar nerve. A thinner

mesotendon links the DDFT to the SDFT medially. Proximal to the carpal canal a large pouch occurs dorsal to the flexor muscles, bulging laterally and medially caudal to the radius if distended. Distal to the carpometacarpal joint the carpal sheath continues as a blind sack between the DDFT and ALDDFT and bulges dorsolaterally to the DDFT in the proximal third of the metacarpal area. The lateral palmar nerve and palmar veins pass within the retinaculum.

Surgical Technique

Several techniques have been described depending on the lesions identified before surgery. Removal of osteochondromata from the caudal distal aspect of the radius has been described using a lateral approach through the distended proximal pouch.^{8,33} The horse is anesthetized and placed either in lateral recumbency with the affected limb uppermost or in dorsal recumbency with the foot attached to a hoist, so that carpal position may be altered during the procedure. This latter position decreases hemorrhage, which may substantially decrease visibility. The carpal sheath is distended with 40 to 60 mL of balanced electrolyte solution, and the endoscopic portal is made between the lateral digital extensor and ulnaris lateralis tendons, 3.5 cm proximal to the distal radial physeal scar. The cannula and blunt obturator are inserted proximomedially into the carpal sheath. The instrument portal is made on the same side as the arthroscope portal, 2 cm distal to it. A medial approach has also been described but appears less practical because of the presence of the ALSDF and the median nerve and artery.⁷

This lateral proximal approach is generally recommended for desmotomy of the ALSDF and removal of osteochondromata or caudal radial physeal exostoses. Desmotomy of the ALSDF is carried out easily via tenoscopy.^{32,33} This approach offers several advantages over the standard "open" medial approach: postoperative swelling is decreased, and the incidence of wound breakdown or seroma is nearly abolished. Intrathecal hemorrhage seems to be better tolerated than with the standard approach. Hence return to training is dramatically shortened (4 to 6 weeks). After insertion of the cannula through a portal 2.5 to 3 cm proximal to the distal radial physeal scar as described above, an instrument portal is created immediately proximal and caudal to the palpable physeal scar. The ALSDF is easily identified by palpation with a blunt arthroscopic probe. In some horses, I use intraoperative ultrasonographic guidance to place needles at the proximal and distal borders of the ligament at the level of the flexor carpi radialis tendon. This also permits identification of the median artery and the small transverse artery, which are best avoided to reduce perioperative hemorrhage. The needles are used as landmarks for desmotomy. I use a radiofrequency hook blade (Saber 30, ArthroCare Corporation) as described for annular desmotomy, but the technique may also be performed using an arthroscopic hook blade, a tenotomy knife, or a No. 15 scalpel blade on a long No. 3 handle. After identifying the distal edge of the ligament, section is commenced at that level in a proximal direction and through the ligament until the sheath of the flexor carpi radialis tendon is entered. The section is continued proximally. The proximal quarter to third of the ligament is located outside the proximal boundaries of the carpal sheath, and this is where the transverse artery may

be inadvertently severed. The radial head of the DDFT is reclined dorsally with the endoscope, and the desmotomy is continued until all identifiable fibers are severed. Using the coagulation setting on the coblation device during the procedure helps avoid hemorrhage. When the section is completed, the cut ends of the ligament separate, showing the large communication with the flexor carpi radialis sheath. There may be tremendous postoperative swelling of the carpal sheath and the flexor carpi radialis sheath; therefore it is recommended that a pressure bandage be placed over the carpal area (see below).

These techniques do not permit examination of the distal half of the carpal sheath. Therefore another technique has been developed to facilitate endoscopic examination of most of the carpal sheath.⁹ The horse may be placed in lateral recumbency with the affected limb uppermost or in dorsal recumbency with the affected limb suspended loosely, so that the carpus is slightly flexed. An 8-mm longitudinal skin incision is made without previous distention of the carpal sheath 1.5 to 2 cm distal to the distal border of the accessory carpal bone along the lateral aspect of the DDFT. A medial approach is not recommended because examination is restricted by the mesotendons and the risk of injury to the median artery and medial palmar nerve. A needle is used to ensure that no vessels are present in the fascia deep to the incision. The incision is extended with a scalpel through the fascia into the carpal sheath. The arthroscope is inserted proximally, between the DDFT and dorsal wall of the sheath. The proximal pouch is large and contains small villi. The radial head of the DDFT forms a conical prominence in the medial aspect of this pouch. Rotation of the endoscope and manipulation around the tendons allow examination of the DDFT and SDFT surfaces, caudal surface of the distal radius, and fibrocartilaginous sheath wall in the carpal canal. Minimal fluid pressure should be used to avoid flexion of the carpus. The endoscope may be inserted between the tendons to view the surfaces and the lateral aspect of the mesotendon, covered by short, thin villi. Redirecting the endoscope distally permits examination of the distal recess. A normal, longitudinal synovial fold appears dorsomedially in the carpal sheath in the distal carpal region. Instrument portals are made where necessary to allow for adequate triangulation.

Improved triangulation is obtained for removal of osteochondromata of the distal caudal radius with this method, although the endoscope may occasionally be too short.

Desmotomy of the carpal palmar retinaculum has been advocated for carpal canal syndrome associated with constriction syndrome or functional carpal ankylosis. The technique may be performed using tenoscopy.³⁵ I use electrosurgery because hemorrhage is often marked, particularly because there is frequently substantial concurrent synovial swelling.

Postoperative care is similar to that described for other sheaths, but postoperative hemorrhage and swelling are very common in the carpal sheath. It may not be practical to apply a pressure bandage for any length of time over the carpus. I usually apply a pressure bandage for recovery from general anesthesia and then replace it after the horse stands. The limb remains bandaged for only 48 hours because of the risk of pressure sores. The horse must be restricted to stall rest for at least 2 to 3 weeks.

Other Tendon Sheaths

Most tendon sheaths may be examined by tenoscopy, including extensor tendon sheaths in the dorsal carpal and tarsal regions. However, no published reports indicate the use of tenoscopy for these smaller synovial cavities, possibly because acceptable results have been obtained with traditional surgical exposure.³⁶ I have attempted tenoscopy of the carpal extensor sheaths experimentally in isolated limbs, using a 4-mm, 30-degree forward endoscope inserted medially or laterally to the tendons, proximal to the carpus. This technique provides acceptable examination of the sheath and tendon surfaces, but little movement is possible because of the tight extensor retinacula.

BURSOSCOPY

Reports of bursoscopy in horses are limited,^{11,37} but it is probable that the technique would yield similar advantages to tenoscopy in horses with masses or infection in normal or acquired bursae. Surgical exposure and debridement of hygromas, capped hocks, and metacarpophalangeal subtendonous bursae are often associated with wound dehiscence and chronic infection.³⁸ However, I am unaware of published data describing bursoscopic examination in these locations. A technique for bursoscopy of the calcaneal bursa of the SDFT has been described and advocated for diagnosis and treatment of injuries to this structure and is probably most useful in horses with infectious bursitis.³⁷

Bursoscopy of the Intertubercular Bursa

Bursoscopic surgery has been used for the management of infectious intertubercular (bicipital) bursitis,³⁹ and a report describes its use as a diagnostic method in a horse with traumatic bicipital bursitis.¹¹ The horse is placed in lateral recumbency with the affected limb uppermost. The endoscope is introduced through a craniolateral skin portal, made over the point of the shoulder, immediately cranial to the lateral (greater) tubercle of the humerus. The bicipital bursa is distended with 40 mL of fluid. The skin incision is continued through the brachiocephalicus muscle and into the bicipital bursa, and the endoscope sleeve and conical obturator are inserted in a caudoproximal direction. A technique using two separate portals has been described to improve visibility.⁴⁰ The first portal is made into the distal recess through an incision immediately proximal to the deltoid tuberosity. For the second portal, an incision is made cranioproximal to the lateral humeral tubercle to view the proximal half of the bicipital bursa. Experience with these techniques is currently limited, but they should provide similar advantages to tenoscopy, including easier access to the bicipital bursa, improved visibility, and decreased postoperative morbidity. This needs to be confirmed by more extensive reviews.

Bursoscopy of the Navicular Bursa

Endoscopic examination of the navicular bursa (bursa podotrochlearis)⁴¹ recently has been described as an alternative to the traditional street-nail procedure.^{42,43} It is the technique of choice for treating infectious navicular bursitis.

The main indication for navicular bursoscopy is for management of a contaminated or infected bursa.⁴¹ Other

indications include diagnostic examination in horses with pain localized to the palmar aspect of the foot but with no lesions identifiable using other imaging modalities and the debridement of adhesions between the navicular bone and the dorsal surface of the DDFT.⁴⁴

Surgical Technique

The technique has been described elsewhere.^{41,44-46} Standard arthroscopic equipment is used, although a thinner, 4-mm diameter or less, endoscope is more practical. The horse is placed in lateral recumbency with the metacarpal or metatarsal region supported and the digit moving loosely. A medial approach with the affected limb lowermost or a lateral approach with the limb uppermost may be used. A vertical, 5-mm skin incision is made along the abaxial border of the DDFT, 1 cm proximal to the cartilage of the foot, and palmar/plantar to the neurovascular bundle. The cannula, with a conical obturator, is inserted distally and slightly axially, dorsal to the DDFT. The obturator is replaced with the endoscope. Rotation of the endoscope allows examination of the entire proximal recess of the navicular bursa and sometimes the distal recess, including the smooth dorsal aspect of the DDFT and palmar fibrocartilage of the navicular bone. The collateral sesamoidean ligaments, blending over the proximal surface of the navicular bone into the fibrocartilage and the distal sesamoidean impar ligament, in the distal recess of the navicular bursa, are covered by synovium with thin villi. The larger proximal pouch and the T-ligament are also covered by synovium.

A wound in the sole, sulci, or frog can be used for insertion of cannulae or instruments into the navicular bursa. Some enlargement of the tract using curettes or a motorized synovial resector may be required but should be minimal to limit damage to the DDFT. If access through the wound is difficult, or to reach a lesion that cannot be accessed this way, a similar approach to that used for the endoscope may be made on the opposite side of the limb.

The navicular bursa is lavaged, and any lesions are debrided sharply. Partial synovectomy may be carried out if necessary. The use of motorized synovial resectors is recommended. At the end of the procedure the opening of a sinus tract on the solar surface of the foot may be enlarged and debrided to avoid abscess formation. Debridement of the defect through the DDFT should be minimal. An aminoglycoside antibiotic may be placed in the navicular bursa, and the skin incisions are closed routinely. A bandage including the whole hoof and extending to the proximal metacarpal or metatarsal region is applied.

Postoperative Management and Results

Postoperative use of antibiotics and NSAIDs is at the surgeon's discretion. The horse can be walked out in hand after 2 or 3 days, and exercise can be gradually resumed after healing of the wound is complete, in the absence of complications.

Complications of infection include recurrence, extension of the infection into adjacent synovial structures, and osteitis or fracture of the navicular bone.^{41,43} Contamination of the distal interphalangeal joint or DFTS may be treated during the initial surgery by an endoscopic approach using the same skin portal.⁴¹ If infection recurs, lavage through needles or bursoscopy may be performed,

and an open approach through the solar surface may be used, but the prognosis should then be considered graver.

The prognosis for horses with infectious navicular bursitis using this approach⁴¹ appears to be greatly improved compared with the more invasive street-nail procedure.⁴³ Seventy-five percent of horses returned to the initial use

after bursoscopy versus 31.5% using the open technique, although the criteria used to judge success may be slightly different.⁴¹ Bursoscopy is considered to be the technique of choice for infectious navicular bursitis, although I recommend using a street-nail approach for the salvage of horses with chronic bursitis with extensive damage to the podotrochlear structures.

Chapter 25

Thermography: Use in Equine Lameness

Andrew P. Bathe

Infrared thermography has been used in equine orthopedics for a number of years.¹ Improvements in imaging quality and technology now yield images that are easier to interpret. The systems are also more cost effective. Thermography pictorially represents the surface temperature of an object and is a noninvasive method of detecting superficial inflammation and thus can have a role in lameness diagnosis. It is a physiological imaging modality, as is gamma scintigraphy, and thus has a lower reproducibility than anatomical imaging modalities such as radiography and ultrasonography. Superficial blood flow is a dynamic system and is likely to be variable and is also prone to artifacts, which has led some people to doubt its clinical applicability. Others consider it useful in the diagnosis of a large number of diverse conditions.² With experience and care in interpretation, thermography can be a useful adjunct to lameness evaluation, as part of an integrated clinical and imaging approach. Eddy and co-workers reported a 63% correlation among thermographic findings in 64 horses and ultrasonography, nuclear scintigraphy, and radiography.³

Heat is lost through the skin by radiation, convection, conduction, and evaporation.⁴ Thermal cameras assess infrared radiation from an object; this is optically focused, collected, and transformed by detector arrays into an electronic signal that in modern systems then generates a real-time video image. The skin and hoof derive their heat from tissue metabolism and local circulation, and because the former is generally constant, variation in superficial temperature normally relates to changes in local tissue perfusion. Radiation from the equine foot and limb is more important than reflection, and lighting levels are not a major concern. Thermographic evaluation of the foot and distal aspect of the limb is complicated by the thermoregulatory role of the distal aspect of the limb, whereby the blood supply can be dramatically reduced to conserve heat in cold conditions.⁵ Thus an understanding of the physiology of the distal aspect of the limb is essential for optimal image interpretation.

Several different thermal imaging systems are available. Older systems were primarily developed for military or industrial applications and are relatively cumbersome and have poor image quality. The top-end systems have a cooling system to ensure temperature stability of the detector, and this increases the fragility of the system and the maintenance costs. Uncooled camera technology is preferable in a veterinary environment because it is cheaper, lighter, and more robust. These systems have become more available recently, and the system cost for diagnostic-quality thermographic imaging is no longer prohibitive. There is still wide variation in the image quality among different systems, and it can be difficult to compare different systems, but the user becomes used to the particular thermal patterns produced by each machine. Some systems are also radiometers and allow an accurate temperature measurement to be obtained, whereas other systems do not measure the absolute temperature but are able to determine the difference between two areas within the same image. Although a radiometer is not essential, it does assist in comparisons among different examinations. Higher image quality leads to a greater ease of interpretation of the image. The quality of image processing software is also improving, but the majority of interpretation is carried out in real time. Images can be stored in a variety of digital formats for archiving and later comparison. Infrared thermographic instrumentation is far more sensitive than human hands in detecting temperature changes in an object. There may be variability of up to 1° C attributed to the camera in clinical imaging,⁶ and differences of over 1° C are normally deemed as being potentially clinically significant in image interpretation.

IMAGE ACQUISITION

Imaging should be performed in a relatively bare room without radiant heat sources, drafts, or sunlight. Some clinicians recommend allowing the horse to thermally equilibrate in the environment in which it is to be imaged. Equilibration can take up to 1 hour, but although the absolute temperature changes, there is little change in the relative thermal pattern.⁶ Thus equilibration is not necessary for clinical imaging. The optimal ambient temperature for imaging is 20° to 25° C. Below this temperature the distal aspect of the limbs are more prone to thermal cutoff,^{5,7} and above this range the contrast between the horse and the background is lost. Thus in colder temperate climates it can be advantageous to have a "hot box" to raise the ambient temperature if thermal cutoff prevents diagnostic imaging. It can also be advantageous to image the feet after the horse has been trotted and lunged, which increases the

Fig. 25-1 • Normal dorsal, palmar, left lateral, and solar thermographic images of the distal aspect of the forelimbs of a horse. There is good symmetry between the limbs. The coronary band is the warmest area, and the rest of the hoof becomes colder in a regular pattern closer to the ground surface. The palmar image shows a normal increase in heat between the heel bulbs. On the solar image there is a V-shaped pattern of increased heat representing the sulci of the frog.

blood supply to the limbs and hence increases the inherent contrast of the digit relative to the background.

A long hair coat acts as an insulator and reduces the contrast within the image. Irregular patterns of clipping, topical applications, and dirt can complicate interpretation of images. Bandages and rugs should be removed at least 20 minutes before imaging. The feet should be clean for thermographic imaging of the digit and should be picked out and brushed to remove external contamination.

The distal aspect of the limb should be imaged from a dorsal position, from a palmar or plantar direction, and from the left and right sides. The limbs are then lifted, and a solar view is obtained of the feet (Figure 25-1; Color Plate 1). The joints of the proximal aspect of the limbs should be imaged cranially and laterally. The neck is imaged from the side. The back and hindquarters should be imaged as dorsally as is possible. Close-up images of regions of interest can then be performed if necessary. Comparisons should be made between sides; it can be helpful to repeat the imaging on another occasion if the results are uncertain.

It is normally most intuitive to image using a rainbow color palette, with as great a range of color depth as the system allows. There is variability in the absolute temperature of the distal aspect of the limb; therefore the thermal range should be adjusted for each individual horse. The coronary band is normally the warmest area within the image, reflecting its high vascularity. The temperature level and span of the camera are adjusted to use the whole color range for the image. The coronary band normally appears white, and the coldest part of the image is blue or black, thus maximizing the visual contrast within the image. Some cameras have an automatic setting that constantly readjusts the image in this way. This does not allow comparison of left-to-right symmetry and thus is not useful clinically.

The camera should be carefully focused, and a series of still images obtained. The absolute temperature of points of interest can be determined using a radiometer so that absolute temperature differences can be calculated. Some systems allow more detailed analysis of the images on a computer, including calculation of mean temperature within regions of interest or graphically along lines of interest. The software tends to be expensive, and there is a greater need for such images in research than in a clinical setting.

CLINICAL IMAGING

Figure 25-1 demonstrates a series of normal images of the distal aspect of the limb and digit. The coronary band is the warmest part of the image, and the hoof becomes progressively cooler toward the ground surface. The bulbs of the heel are also warm. On the solar image, the frog sulci appear warmest, as there is less tissue depth in this area. Heat generally follows the pattern of blood vessels so the medial metacarpal region is normally warmer than the lateral. Ideally the limbs appear symmetrical, but there can be variation in normal horses, especially at low ambient temperatures.^{4,5} Thermoregulatory cutoff is variable, and there are intermittent periods of vasodilatation, which is not necessarily symmetrical between left and right⁴ nor front and hind feet. Reevaluation of the horse some hours later may yield a different image. Exercising the horse for approximately 20 minutes or administering vasodilators such as acepromazine can increase the temperature to allow diagnostic imaging. Thermoregulatory cutoff in the distal aspect of the limb dramatically reduces the temperature and thus the contrast; therefore, subtle lesions may be missed. However, severe inflammation causes a sufficiently increased blood flow to be detectable.

Thermography is sensitive at detecting the presence of superficial inflammation within the foot, and in my opinion this is one of the more useful areas to image clinically.⁸ Conditions such as subsolar or coronary band infections result in a marked increase in temperature; corns and subsolar bruising may also be associated with increased temperature. Horses with chronic palmar foot pain and navicular syndrome do not show superficial inflammation and have either normal thermographic patterns or a colder pattern than normal, especially in the heel region. The temperature in the heel does not increase after the horse is exercised,^{6,7} probably because of a decrease of loading in this area rather than inherent ischemic disease. Superficial foot inflammation can obviously be diagnosed clinically without thermographic imaging in the majority of horses. Thermography is helpful in horses for which there is the suspicion of deep pathology, but also for those with mild signs of inflammation and response to hoof testers. Thermography can be helpful in optimizing the efficiency of a lameness evaluation, especially close to competition and in an extremely fractious horse, where it is advantageous

Fig. 25-2 • An advanced event horse with previous history of midbody superficial digital flexor tendonitis of the right forelimb. More recently peritendinous edema had developed distally in the right forelimb. Ultrasonographic images show increased cross-sectional area of the superficial digital flexor tendon, and areas of hyperechogenicity and hypoechogenicity. It was not possible to determine if there was active pathology or if this was the level of healing that had been reached from the previous injury. The palmar thermographic image shows rectangular clip artifacts on both limbs. There is a clinically significant increase in temperature of the distal palmar aspect of the right forelimb compared with the left, indicating inflammation, and thus the image suggests recurrent tendon injury.

to minimize the amount of diagnostic local analgesia employed. Thermography can also be used to assess foot balance. When a horse with metal shoes is trotted on a hard surface and immediately imaged, the side taking the greatest load appears warmer when the shoe is imaged. In horses with substantial mediolateral imbalance that land lateral wall first and roll over to the medial side during weight bearing, there can be an increased temperature over the coronary band medially, rather than on the side that lands first.

Thermographic evaluation can also be useful in monitoring laminitis. In acute laminitis there is increased heat within the foot.⁴ The normal gradation of temperature from the coronary band to the sole is lost as the temperature on the dorsal hoof wall approaches that of the coronary band. On solar images there may be an increased temperature in the region of the tip of the distal phalanx. In chronic laminitis there may be areas of decreased temperature in the dorsal aspects of the coronary band and the hoof wall, indicating decreased perfusion and laminar separation. This is a poor prognostic indicator.

Joints are best evaluated from the dorsal aspect and tend to be cool in comparison to surrounding tissues except where there are superficial vessels. Acute inflammation can occasionally give an increased heat pattern, but chronic pathology is not normally detectable. Early signs of joint inflammation can reportedly be detected 2 weeks before lameness resulting from osteoarthritis in Thoroughbred racehorses,⁹ allowing modification of training regimens to decrease the risk of serious injury.

The superficial digital flexor tendon (SDFT) can be usefully imaged thermographically. The midportion of the tendon is bilaterally symmetrical, whereas the proximal and distal portions are reduced in temperature. The majority of horses with tendonitis have localizing clinical signs and ultrasonographic abnormalities. Thermography can be useful as a routine screening procedure when dealing with a large number of horses in training, to help identify

subclinical pathology (see Figure 117-5). It can also be useful in a horse with recurrent tendonitis, with preexisting ultrasonographic abnormalities, in which it is important to determine if there is inflammation and recurrent injury (Figure 25-2; Color Plate 2).

Ligaments are more difficult to image. The proximal aspect of the suspensory ligament is positioned deeply, and in my experience there is no characteristic thermal pattern associated with desmitis. The midbody of the suspensory ligament may have increased temperature if it is inflamed, and thermography can be useful to accurately localize inflammation in horses with complex pathology affecting the splint bone and/or suspensory ligament. Active suspensory branch desmitis may be detected thermographically.

The majority of long bones are covered in muscle and cannot be imaged thermographically. However, the dorsal aspect of the third metacarpal bone can be evaluated in horses with sore shins. Thermography may be useful for screening and for grading of severity of injury.²

Muscle inflammation can be identified as areas of increased temperature, although some acute injuries with edema appear cool¹⁰ (Figure 25-3; Color Plate 3). This is clinically useful, as the clinical localization of muscle strains can be difficult. Look for a consistent left-right asymmetry.

The neck should be bilaterally symmetrical, with care taken that the camera settings are not altered between the two sides. It can be helpful to reevaluate the first side after assessing the contralateral side, to ensure that any differences are genuine. Some horses with cervical pathology have interference with the sympathetic outflow and may show increased superficial blood flow at the affected dermatomes (Figure 25-4; Color Plate 4). The back has a normal, central stripe of increased temperature. Imaging laterally is prone to artifacts, and the images should be obtained as far dorsally as possible from an elevated position behind the horse. Some people image using the reflection from a stainless steel mirror positioned at an angle above the horse. The diagnosis of neck and back lesions is controversial.

Fig. 25-3 • Three examples of muscle injury. The left thermographic image shows a left gluteal injury with increased heat signature. The middle image shows an increase in heat over the biceps femoris muscle. The right image is of a chronic gluteal injury with fibrosis, which has a cooler thermal pattern.

Fig. 25-4 • The left and middle thermographic images are caudodorsal views of the back, showing areas of increased heat associated with clinical signs of back pain and impinging dorsal spinous processes evident radiologically. The lateral view of the neck is from a horse with marked caudal cervical facet joint osteoarthritis. There is an increase in superficial blood flow in this region.

Some use thermography to guide acupuncture or osteopathic treatment¹¹ and consider that back pain can be a sympathetic associated pain syndrome. I tried sympatheticolytic drugs in a number of horses with back pain and saw improvement neither in the thermographic nor the clinical signs. In my experience thermography can detect areas of back inflammation associated with muscle injuries, impinging dorsal spinous processes, or supraspinous ligament injuries (see [Figure 25-4](#)), although the sensitivity and specificity are poor. It may be useful as part of a combined imaging approach. Thermography may also be helpful in assessment of saddle fit.

Thermography has also been used to detect methods of counterirritation¹² and is being employed by the Fédération Equestre Internationale at competitions as an adjunct to medication control.

CONCLUSION

Thermographic imaging can be a useful adjunct to a standard lameness and orthopedic evaluation. It requires a considerable investment of time to gain the necessary experience to differentiate between normal variation and patterns suggestive of pathology. Improvements in technology have brought high-quality imaging within the reach of the equine practitioner, which consequently makes image interpretation much easier. A standard protocol for imaging is important for obtaining accurate results, as is critical evaluation of the findings to integrate them into the total clinical picture. Although not necessary in the vast majority of horses with lameness, there are some horses in which thermography can be helpful. It has roles in screening populations of horses in training to pick up early signs of disease.

The Foot

Chapter 26

The Biomechanics of the Equine Limb and Its Effect on Lameness

Alan Wilson and Renate Weller

Biological structures (and sometimes those engineered by man) break, as a result of either a one-off (single event) load that exceeds their mechanical capacity or, more commonly, chronic fatigue overload, in which repeat micro-failures over time lead to failure of the whole structure. Biological tissue has the unique ability to adapt to mechanical demands and to repair itself given an appropriate mechanical stimulus and sufficient time. Complete failure of a structure happens only if the damage over time exceeds adaptation and repair.

Like man-made structures (e.g., elevators, bridges), biological designs have an inherent safety factor, defined as the ratio of the maximum stress a structure could withstand until breakage and the stress it is most likely to undergo during its lifetime. It is rather comforting that most engineered devices have a safety factor of up to 10 (so next time you read that an elevator has a maximum capacity of 18 people, know that it would actually hold 180!). Unfortunately, the safety factors¹ of equine bones and tendons are approximately 1.5 to 2.

Box 26-1 provides short definitions of biomechanical terms used in this chapter.

WHEN DO MUSCULOSKELETAL STRUCTURES FAIL?

The parameters that influence failure of a musculoskeletal element are the force (magnitude, frequency and number of cycles, speed and duration of loading) the structure experiences and its ability to withstand it. The force on an individual part is related to the force that the whole limb experiences. Force is determined by body mass, speed of locomotion, and the leverage that force has on the specific part. A structure's ability to withstand force is determined by its structural properties, which in turn depend on its material properties and its dimensions. These reflect

the magnitude and direction of the forces acting on it. Forces causing deformation include tension, compression, bending, and shear. Most structures are subjected to and are optimized for one predominant force, but they also have to be able to withstand other forces in normal use and even more so in exceptional circumstances. Tendons experience predominantly tensile forces, whereas joints are subjected to mainly compressive and some shear forces. Bones experience bending, with compressive forces on the concave side and tensile forces on the convex side. Bones have to withstand not only compressive forces from the horse's weight, but also the forces exerted by muscles and tendons that attach to them.

Failure in a live horse is much more complex than simple mechanics, because adaptation, repair, and compensatory mechanisms must be considered. Lameness may be not only a response to pain but also a compensatory mechanism, because it often results in an unloading of the affected limb or structure.

Elements of the musculoskeletal system have to fulfill four main requirements: force transmission without excessive deformation and fracture; use of the least amount of material to keep the metabolic costs for maintenance, transport, and regeneration down; and enough reserve of strength to cope with overload in the case of an accident.² Thus there is a trade-off between safety factors and energy costs. In horses the balance is shifted in favor of keeping the energy costs low while accepting a relatively high risk of musculoskeletal injury. Tendons (such as the equine digital flexor tendons or the human Achilles tendon) need to stretch to store energy in locomotion; to perform this role they need to reach high strains, which places them at a high risk for mechanical overload and damage.

In the following sections we describe the functional anatomy of the horse's limb and the material properties of its components. We discuss the influence of locomotion and the effects of conformation and farriery intervention on the loads acting on the musculoskeletal elements, such as bones, tendons, and joints. We also consider how the loads acting on the musculoskeletal system are changed with certain musculoskeletal disorders.

FUNCTIONAL ANATOMY OF THE HORSE LIMB

Horses have the ability to run fast over short distances (racing speeds reach 21 m/sec [75 km/hr]) and also to cover long distances at slower speeds with a low energy cost of locomotion. This was of evolutionary advantage because it enabled them not only to outrun predators but also to migrate to forage on the rather sparsely vegetated prairie land they originally inhabited. To achieve two

BOX 26-1

Definition of Common Terms in Biomechanics

Duty factor: Ratio of stance time and stride time. Expressed as either a fraction (between 0 and 1) or a percentage (between 0% and 100%).

Ground reaction force: Reaction force exerted from the ground onto the limb of a horse as a reaction of the force exerted by the horse onto the ground. Often split into three components: vertical (weight support), craniocaudal (acceleration and deceleration), and mediolateral (turning and balancing).

Kinetics: Study of the forces acting on bodies.

Kinematics: Study of the movement of bodies.

Safety factor: Ratio of a structure's strength to the maximum stress that the structure is likely to experience over its lifetime.

Stance phase (contact phase): Time the limb is in contact with the ground, from initial contact (foot on) to liftoff (toe off).

Stiffness: Force required to achieve a certain change in length. Slope of the force-length curve; the stiffer the structure, the higher the stiffness and the steeper the force-length curve.

Strain: Length change of a structure in relation to its starting length (e.g., through compressive or tensile load), often expressed as a percentage of the original length of the structure.

Stress: Force per unit area; also called *pressure*.

Stride time (duration): Time taken for a full stride cycle—for example, between foot contact of a limb to the following foot contact of the same limb. In general, the stride time decreases with increasing speed.

Swing phase (protraction): Time the limb is not in contact with the ground.

Stride frequency: Number of strides taken per second, measured in strides per second or Hz.

diverse locomotive requirements, the horse developed anatomical features that promoted energy efficiency (after all, it would not do the horse any good if it had to spend more energy to get to the food than could be gained by eating the food, or to get eaten in the process).

Although most veterinarians are familiar with some energy-saving mechanisms, such as the unguligrade stance of the horse, the patellar locking mechanism, and the stay (reciprocal) apparatus, from standard textbooks, there are many more features that play a major role in ensuring energy-efficient locomotion. This section concentrates on the musculoskeletal adaptations of the equine limb; however, a more comprehensive overview of general anatomical features is given elsewhere.³

Horse Limbs Function Like Pogo Sticks

If you tried to build a horse limb with children's blocks, the limb would collapse, because it would be impossible to build the fetlock joint in a hyperextended position. However, in a live limb the digital flexor tendons and ligaments on the flexor side of the limb prevent failure. Tendons have elastic properties and act like rubber bands or springs, providing resistance against which the limb presses when it comes under load, thus resisting further hyperextension and preventing collapse (Figure 26-1). The tendons are stretched at the same time, thus storing elastic strain energy, which can be returned in elastic recoil. During each step energy is stored, and it is returned when the limb leaves the ground. Energy is carried forward from one step to the next, thus reducing work the muscles have to do and saving metabolic energy. Indeed, the muscles associated with the main contributors of this system—the suspensory ligament

(SL), deep digital flexor tendon (DDFT), and superficial digital flexor tendon (SDFT)—either are not present at all (the SL and the accessory ligament of the DDFT [ALDDFT]) or are very short in relation to the tendons (e.g., the average length of the deep digital flexor muscle-tendon unit in a Thoroughbred is 77 ± 5 cm, more than 60% of which is tendon. The flexor muscles, being highly pennate and having short muscle fibers (1 cm in length), have limited capacity to change the length of the muscle-tendon unit when contracting. Approximately 7% of the energy stored in the tendons is released as heat, and during gallop the tendons of a galloping horse reach about 45°C .⁴ We have reasoned that increase in temperature may account for core lesions in equine SDFTs but found that although 45°C resulted in death of some cells, tendon cells may be resistant.⁵ Core lesions may result from hyperthermic damage of matrix components.⁵

Like any springlike structure, the limb itself has a certain stiffness, which is a measure of how much it shortens for a given load. A whole equine limb changes length mainly as a result of fetlock extension and length changes in the digital flexor tendons.⁶ People can adjust their leg stiffness by muscle contraction to suit the softness or hardness of the ground on which they are walking or running.⁷ Horses cannot adjust their leg stiffness because of the limited ability of the flexor muscles/tendons to change length, and this may be the reason why some horses cope better than others on different goings (footings). The flexor muscles do, however, damp vibrations, which otherwise would be likely to cause injury to musculoskeletal tissues.⁸

Bones

To enable a pogo-stick design, the bones in the equine limb are reduced compared with other animals: the radius and ulna are fused, and the horse bears weight only on the third metacarpal bone (McIII) or third metatarsal bone and the digit. Fewer bones allow lengthening of the limb and tendons and reduction of the mass of the distal aspect of the limb. This increases the energy storage capabilities of the digital flexor tendons and also results in a lighter limb that can be swung more rapidly and with less energetic cost, which is of benefit in locomotion. Fewer bones is thus an adaptation for maximum strength with minimum weight, because the bending strength is much higher for one large bone than for the same amount (and hence weight) of material arranged as several smaller bones.² However, a reduction in bone mass for energy efficiency results in an increase in fracture risk, and this is reflected in the fact that the distal limb bones are at higher risk for fracture than the proximal limb bones.⁹

Synovial Joints

Joints fulfill two main mechanical functions: they allow the movement of limb segments in relation to each other, and they act as shock absorbers. Limb movement is limited to the sagittal plane by anatomical adaptations of the phalanges and the fusion of bones, and only small, out-of-plane movements, such as adduction and abduction or rotation, are possible. Movement is further limited by the anatomical features of some of the articular surfaces, such as the interlocking configuration of trochlear and sagittal ridges and matching grooves, and is enforced by collateral ligaments. Without the need for muscular control, these

Fig. 26-1 • Anatomical drawing of an equine forelimb (*left*) and the equine forelimb modeled as a spring-system (*right*); superficial digital flexor tendon (SDFT); deep digital flexor tendon (DDFT); accessory ligament (AL) of the DDFT; and AL of the SDFT. Limbs function like pogo sticks: the hyperextended fetlock joint is kept from collapsing by the springlike digital flexor tendons on the palmar aspect of the limb. When the limb comes under load during the stance phase of the stride, it compresses by further extending the fetlock joint while stretching the digital flexor tendons. This enables the digital flexor tendons to store elastic energy, which is released for propelling the limb into the swing phase. *MCP*, Metacarpophalangeal; *PIP*, proximal interphalangeal; *DIP*, distal interphalangeal.

features restrict joint movement to the sagittal plane, thus further decreasing metabolic costs.

Although all joints provide movement and shock absorption to a certain degree, some joints allow only a small range of movement and have the primary function of shock absorption, whereas other joints have a large range of movement and a primary function of movement. These joints can be functionally classified as low-motion or high-motion joints, respectively. The fetlock joint, a good example of a high-motion joint, goes through 90 degrees of movement during the stance phase of gallop, whereas the proximal interphalangeal joint has a range of motion of only 5 to 10 degrees. In complex joints such as the carpus and tarsus, there is a division in function: both the antebrachioacarpal and tarsocrural joints are high-motion joints, but in the more distal joints of the carpus and tarsus there is less movement; the least movement is in the carpometacarpal and tarsometatarsal joints. There is also a difference in occurrence and clinical severity of

skeletal disorders between high- and low-motion joints. Osteochondrosis is much more common in high-motion joints, and osteoarthritis (OA) is usually of greater clinical significance than in low-motion joints.

The Foot as Interface to the Ground

The foot provides the interface between the horse and the ground. It is a complex modification of integument surrounding, supporting, and protecting structures in the distal limb of the horse. The hoof capsule encases within a confined space three bones, a series of ligaments and tendons, two synovial structures, a digital cushion, cartilages of the foot, blood vessels, and nerves. Although the horny hoof capsule provides protection of the internal structures, it does not allow for expansion through swelling; therefore any swelling that does occur as a result of injury leads to an increase in pressure and thus stimulation of pain receptors. Mechanically the foot has three main functions: shock absorption when the foot comes into

Fig. 26-2 • Schematic drawing illustrating two of the shock-absorbing features of the equine foot. First, the shape of the solar surface with the frog in the middle and the frog grooves on either side allows the heels to move sideways and distally on ground contact, while the toe retracts. Second, the suspension of the distal phalanx within the horn capsule allows forces to be transferred from the distal phalanx across the laminar junction to the hoof and to the ground via the distal border of the hoof wall. GRF, Ground reaction force.

contact with the ground, support and grip when the limb is bearing weight, and propulsion when the limb leaves the ground. It must also resist excessive abrasion and protect sensitive structures lying internally, while, in wild horses, allowing sufficient natural wear of the wall to maintain hoof shape.¹⁰

The foot has a series of “built-in” protective mechanisms that absorb part of the concussive forces and damp vibrations during impact (Figure 26-2):

1. The shape of the solar surface with the frog in the middle and the frog sulci (grooves) on either side allows the heel to move sideways and distally on ground contact while the toe retracts.
2. The suspension of the distal phalanx within the horn capsule allows forces to be transferred from the distal phalanx across the laminar junction to the hoof and to the ground via the distal border of the hoof wall.
3. The digital cushion located under the frog and sole between the cartilages of the foot is a wedge of elastic subcutaneous tissue, consisting of collagen, elastic fibers, islands of cartilage, fat, and modified skin glands; this cushion aids in shock absorption by deforming and permitting the frog to move. The

equine digital cushion, however, is small in comparison to that in other species—for example, the elephant limb, which relies heavily on its large digital cushion for shock absorption.

4. The hoof has the ability to slide along the ground surface.
5. The distal interphalangeal (DIP) joint can move by rotation and translation.

ABILITY OF STRUCTURES TO COPE WITH MECHANICAL DEMANDS

Structural and Material Properties

When a force is applied to a structure, the structure usually responds by deforming. The greater the force applied to a structure, the greater the deformation. The ability of a structure to resist deformation is expressed as stiffness and represents the slope of a structure’s force-length relationship. The force-deformation relationship of biological structures behaves in a roughly linear elastic manner until the applied load causes nonreversible deformation and ends in failure. The force-deformation relationship describes the structural properties and depends on the material properties of a tendon and on its dimensions. Larger structures are able to cope with larger forces: imagine two ropes made of the same material, but double the cross-sectional area (approximately 1.41 times the diameter); the thicker rope will be able to withstand double the force of the thinner one.

It is often of interest to know about the properties of the material per se, independent of size. This is achieved by dividing the force acting on a structure by its cross-sectional area. When normalized for cross-sectional area, a force is called *stress* (σ ; common units would be mega Newtons per square meter [MN/m²] or Newtons per square millimeter [N/mm²]). The resulting deformation of an applied stress is expressed as *strain* (ϵ), the ratio of the change in size to the original size. Being a ratio, strain does not have a dimension; however, it is often expressed as a percentage—for example, $\epsilon = 0.1 = 10\%$. If we are interested in the property of a material rather than structure, we can express this relationship as a stress-strain curve. The slope of this curve is the ratio between the tensile stress and strain and is called the *elastic modulus* or *Young’s modulus* (E). The elastic modulus defines whether a material is “rigid” or “compliant.” Rigid materials have a very high elastic modulus and deform very little under load, whereas compliant materials have a low elastic modulus and require less load to deform. Bone, for example, is relatively rigid, whereas articular cartilage is more compliant and thus is able to act as an excellent shock absorber by undergoing considerable deformation when under load. Figure 68-1 shows the stress-strain curves for the digital flexor tendons of a Thoroughbred racehorse.

The ability of structures to deform when loaded and return to their original length when the load is removed allows them to store energy. The amount of energy per unit volume is the area under the linear portion of the stress-strain curve. The capacity of a material to absorb and release energy is often referred to as *elastic resilience*. The energy a material can absorb before failure defines whether it is “brittle” or “tough”: tough materials are able to absorb

considerable elastic energy before failing, whereas brittle materials absorb very little. The digital flexor tendons of a horse are able to store and return a considerable amount of energy during locomotion. Load-deformation curves of tendons are different between loading and unloading, forming a “hysteresis” loop. The area of the loop presents the loss of energy, largely in the form of heat, that occurs during stretch and release (see Figure 68-2). It has been shown that the heat produced by repetition of this mechanism leads to an increase in core temperature, which may contribute to the pathogenesis of tendon injury through thermal damage.⁴ A detailed description of the pathobiology of tendon injuries is given in Chapter 68.

From an injury perspective, stress is probably the most informative mechanical measure in addition to strain. Equine digital flexor tendons, for example, have different elastic moduli and experience different strain rates *in vivo*, but they also have different cross-sectional areas. Both the SL and the SDFT experience high strains (up to 16%) during locomotion, but the stress in the SDFT is much higher than in the SL because its cross-sectional area is only about a third of that of the SL.¹¹ This corresponds to the fact that the SDFT is the most commonly injured tendon or ligament (see Chapter 68).

Changes in Structural Properties

Structural properties change constantly (within limits) either through changes in dimensions or material properties, and this is likely to have an effect on the risk of musculoskeletal injury. Structural properties change with age, in response to loading, and through pathological processes. Changes in dimensions are most obvious for muscle, where exercise leads to an increase in muscle volume. Change in the external dimensions of bones, tendons, and ligaments is limited. These tissues, especially bone, respond predominantly by modifying internal structure. Most biological materials have a variety of components, each of different stiffness—for example, in the case of bone, collagen fibers, and minerals. Mechanical properties can be altered by changing the relative quantity of the components. For example, bone becomes stiffer with higher mineral content, which makes it stronger but diminishes its capacity to absorb energy on impact, making it more brittle. This suggests that there is a trade-off among stiffness, strength, and energy absorption. Chapter 68 summarizes how an equine digital flexor tendon responds to external stimuli.

Not all biological tissues react to stimuli in the same way. Tissue-specific responses play a role both in the pathogenesis of musculoskeletal injury and in how training and rehabilitation programs are designed. Problems can develop when a regimen designed to increase, for example, bone strength may be counterproductive for tendons or joints.

Locomotion and Its Effect on Musculoskeletal Tissues

For quantification purposes, locomotion can be divided into strides: a complete cycle of footfalls (e.g., from the time the left front foot hits the ground to the next time it hits the ground). Each stride can be subdivided into the time the foot spends on the ground (stance phase) and the time the foot is in the air (protraction or swing phase). The ratio between these two is often calculated as a

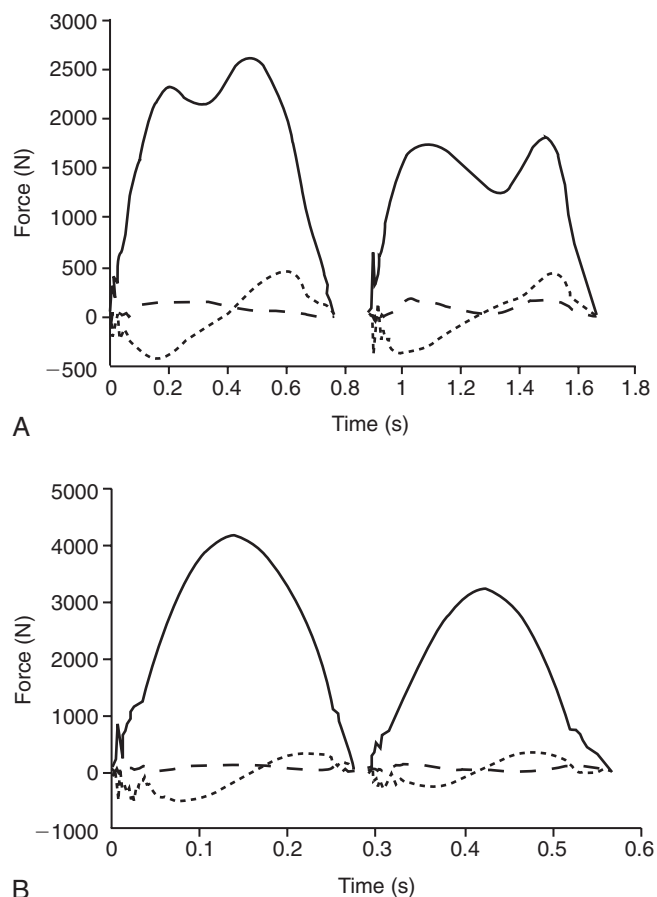

Fig. 26-3 • Ground reaction forces (GRFs) for subsequent forelimb (left “humps”) and hindlimb (right “humps”) stance phases in walk (**A**) and trot (**B**) for a 420-kg horse. Solid lines represent vertical force, short-dashed lines craniocaudal force, and long-dashed lines mediolateral force. For walk and trot, vertical peak force and impulse (area under the curve) are higher in the forelimb than in the hindlimb. Craniocaudal force shows the typical sinusoidal shape with decelerative (negative) force in the first half of stance and accelerative (positive) force in the second half. Mediolateral force is generally low in value and often more variable than the other two components of GRF. **A**, Walk: typical double-humped shape of the vertical force can be seen in both limbs. Here, vertical force reaches a maximum of approximately 62% body weight in the forelimb and approximately 45% body weight in the hindlimb. **B**, Trot: typical single-humped shape of the vertical force can be seen in both limbs. Here vertical force reaches a maximum of approximately 100% body weight in the forelimb and approximately 75% body weight in the hindlimb.

dimensionless parameter for gait characterization and is called the *duty factor*. In relation to (distal-limb-related) lameness, the stance phase is of more interest than the swing phase because the load on the limb is highest during that time. The stance phase can be divided into three main parts: impact, loading, and propulsion.

When the limb is on the ground it experiences a force, the ground reaction force (GRF) (Figures 26-3 and 26-4). The GRF is a function of mass and gravitational force ($F = \text{mass} \times \text{acceleration}$), has a magnitude and direction, and is usually described as a vector. The point underneath the foot where the force is applied is called the *point of zero moment* (PZM). The PZM and the direction and magnitude of the force vector change during the period of the stance phase. Depending on the PZM and the direction of the GRF vector, the force vector does not necessarily go straight

Fig. 26-4 • Schematic drawing of vertical ground reaction force (y-axis) over time (x-axis) of an individual limb in a trotting horse. Each of the three graphs represents a first stance phase followed by a swing phase and a second stance phase of the same limb. Different lines indicate different speeds (long dashes, slow; short dashes, medium; dotted line, fast) and thus different stance times (for simplification purposes, stride time is assumed to be constant). With increasing speed, a decrease in stance time is observed, which results in an increase in peak vertical force (the maximum force achieved during midstance) that is inversely proportional to duty factor (ratio of stance time over stride time). The black horizontal line represents the average vertical force produced by the limb, which needs to be sufficiently large to support the body of the horse against the effect of gravity (i.e., approximately 30% body weight for each individual forelimb or approximately 20% body weight for each individual hindlimb).

through the center of rotation of the joints but might be located dorsally or cranially to it. This creates a lever for the GRF (commonly referred to as the *moment arm*) acting on the joint. The resulting rotational force (also called *torque*) causes the joints in the distal aspect of the limb to extend. This extension moment is counteracted by a flexor moment created by the digital flexor tendons and their moment arms on the palmar or plantar aspect of the limb (Figure 26-5). To prevent the limb from collapsing, the extensor moment has to equal the flexor moment:

$$\text{Fext} = \text{GRF} \times \text{Moment arm GRF} = \text{Fflex} = \text{Force tendons} \times \text{Moment arm tendons}$$

where Fext is force of the extension moment and Fflex is force of the flexion moment. The moment arm of the digital flexor tendons is the distance from the center of rotation of the joint to the line of action of the tendons. The length of the tendon moment arm is largely determined by the size of the proximal sesamoid bones at the level of the fetlock joint and the distal sesamoid bone at the level of the DIP joint. Because the size of these bones remains constant, any change in the magnitude and/or direction of the GRF will have an effect on the force the flexor tendons experience. As the DDFT wraps around the distal sesamoid (navicular) bone, it exerts a compressive force on the bone that is proportional not only to the force the tendon experiences but also to the angle of the path of the DDFT.^{12,13}

Impact

The foot of a galloping horse hits the ground at about 5 m/sec. On first contact with the ground the leg decelerates rapidly, which is reflected in the early increase in GRF (see

Fig. 26-5 • Schematic drawing of the equine forelimb with the direction of the ground reaction force (GRF) vector and its moment arms around the metacarpophalangeal (MCP) joint. To prevent the limb from collapsing, the extension moment is counteracted by a flexor moment created by the digital flexor tendons (here limited to the deep digital flexor tendon) and their moment arm (MA) on the palmar aspect of the limb. As the limb comes under load, the GRF moment arm around the MCP joint increases (shaded arrow). Changes in moment arms of the flexor tendons around the MCP joint are largely determined by the size of the proximal sesamoid bones and remain relatively constant ($\text{MA}_{\text{tendon}}$). Hence an increase in extensor moment results in an increase in the force in the digital flexor tendons. This holds true for static conditions, but the situation during movement is more complex.

Figures 26-3 and 26-4).¹⁴ This energy is dissipated by the foot sliding through and penetrating into the surface and by muscles within the limb. The forces at impact are lower than those experienced in the rest of the stride, but the load is applied very quickly, which appears to be important in eliciting musculoskeletal injury. The impact “shock” also causes the limb to vibrate at about 35 Hz, somewhat like the plucking of a violin string. This vibration is predominantly in a horizontal direction and is caused by the large amount of elastic tendon tissue contained in the equine limb and the pogo stick-like lever system. Vibration is apparent in both forelimbs and hindlimbs, but the

vibration amplitude and duration are greater in the forelimbs. The vibration may, in itself, cause damage through increasing loading rate and the number of loading cycles experienced by the tendons. It also has a potent remodeling stimulus on bone and perhaps other tissues.

The magnitude of the vibration is dependent on several factors. Surfaces that allow the foot to slip at impact (or on hard surfaces, a shoe that slips at contact) dissipate the impact energy and reduce the impulse that causes the vibration. Surfaces with good damping characteristics absorb the vibration energy rapidly. This feature is different from the stiffness of a surface, and it is possible to have a surface that is relatively stiff (firm) but has good damping characteristics. The foot as the interface between the body and the ground has several built-in damping mechanisms (see earlier), but the other important damping system is the muscles. Active muscles absorb energy during small-amplitude, high-frequency oscillations. The digital flexor muscles have extremely short fibers and a large physiological cross-sectional area, which means that they can develop high forces but only over a length change of a few millimeters. This arrangement makes them ideal for absorbing the energy associated with a small-amplitude vibration.⁸

Impact characteristics differ among gaits, speeds, surfaces, and shoes.¹⁴⁻¹⁷ The absolute length of the hoof-braking period is 30 to 50 milliseconds, independent of speed,¹⁴ but is affected by the type of surface. In a comparison of all-weather waxed tracks to crushed-sand tracks, the former was found to reduce the amplitude of the shock at impact and the associated vibrations in French trotters.¹⁸

Peak Force

After initial ground contact the limb is loaded in a distoproximal manner,¹⁹ with the whole limb shortening toward the ground, largely because of further extension of the fetlock joint⁶ but aided by rotation and translation of other segments. This prolongs the impact time and extends the period of braking, which makes the limb an effective shock absorber.²⁰

The peak GRF increases with the body mass of the horse. The damage a force can cause depends not only on its magnitude, but also on how quickly it is applied. Force over time is called *impulse* and represents the area under the force/time curve (see Figure 26-4). The shape of the force/time curve is different between forelimbs and hindlimbs and varies for different gaits (see Figure 26-3) and speeds (see Figure 26-4). Impulses are highest during gallop and increase with speed within a gait. At top speed a racehorse's front foot is on the ground for only about 80 milliseconds or 17% of the stride, and the limb experiences a peak force of about 2.5 times body weight. This load is applied in only 40 milliseconds. The load on a hindlimb is considerably lower at about 1.5 times body weight. This difference in peak load may explain, in part, why hindlimbs experience a lower incidence of tendon and ligament injuries.

Speed is a function of stride frequency and stride length. An increase in speed can be achieved by increasing either of these factors; however, neither of these can be increased endlessly. Maximum running speed is constrained by the speed at which the limbs can be moved and by the GRF they can withstand. People sprinting bends change the duration of foot contact to spread the time over which the

load is applied to keep limb force constant. Racing greyhounds do not change their foot-contact timings, and so have to withstand a 65% increase in limb forces; thus in this species limb force does not limit running speed.²¹ It is currently not known if limb force limits running speed in horses as in people or if horses are more like greyhounds.

It is known that individual horses adopt different locomotor strategies to achieve the same speed—for example, horses with longer limbs have lower stride frequencies than horses with shorter limbs.²² An increase in stride frequency can be achieved by reducing the time that either the foot is off the ground (protraction time) or the limb is on the ground (stance time). Protraction time accounts for approximately 80% of the stride time and remains relatively constant during gallop.²³ Changes in stride frequency must be largely achieved through minimizing stance time. It has been shown in people that the forces a limb experiences increase with decreasing stance time, and it is reasonable to assume that the same is true in horses. This may suggest that horses that increase speed by reducing stance time are at higher risk of musculoskeletal injury. However, with an increased stance time comes an increase in the angle a limb sweeps through while the limb is on the ground and the body continues moving over it. This is probably related to an increase in the moments acting on musculoskeletal structures. However, the potential effect of this on musculoskeletal injury has not yet been investigated.

The tissues of the distal aspect of the limb function within a narrow safety margin; this is partly the result of minimizing distal limb mass but also a prerequisite of having tendons that function as elastic energy stores (because energy stored is a direct function of the square of the elongation of a tendon). The force acting through the limb is multiplied by the lever system of the distal limb to impose much higher forces on the bones and tendons of the distal aspect of the limb. These forces approach the mechanical capacity of these tissues, and a small increase in peak load results in a substantial reduction in the number of cycles to failure for the tissue. The relative load distribution between the individual digital flexor tendons also varies by, for example, the angle of the foot to the ground (resulting from either shoe design or the way the foot penetrates into the surface). Elevation of the heel results in a transfer of load from the DDFT to the SDFT and the SL (Figure 26-6).

Number of Loading Cycles

Large volumes of high-speed exercise may exceed the fatigue life of the high-stress tendons and bones. The fatigue life of these tissues (in number of cycles to failure) depends on the peak strain (deformation) experienced; a small increment in strain results in a substantial reduction in the fatigue life of a tissue. The volume of high-speed exercise applied to a horse is therefore critical. High-speed exercise is also the most potent stimulus for eliciting changes in structural properties, so there is a trade-off between providing this stimulus and exceeding the mechanical capacity of these tissues. A galloping horse imposes about 220 loading cycles per mile (strides) on its bones and tendons at a fast gallop and about 360 strides per mile at a canter. These structures have been estimated to have a fatigue life of as little as 10,000 cycles. The relationship between speed and number of cycles to failure is

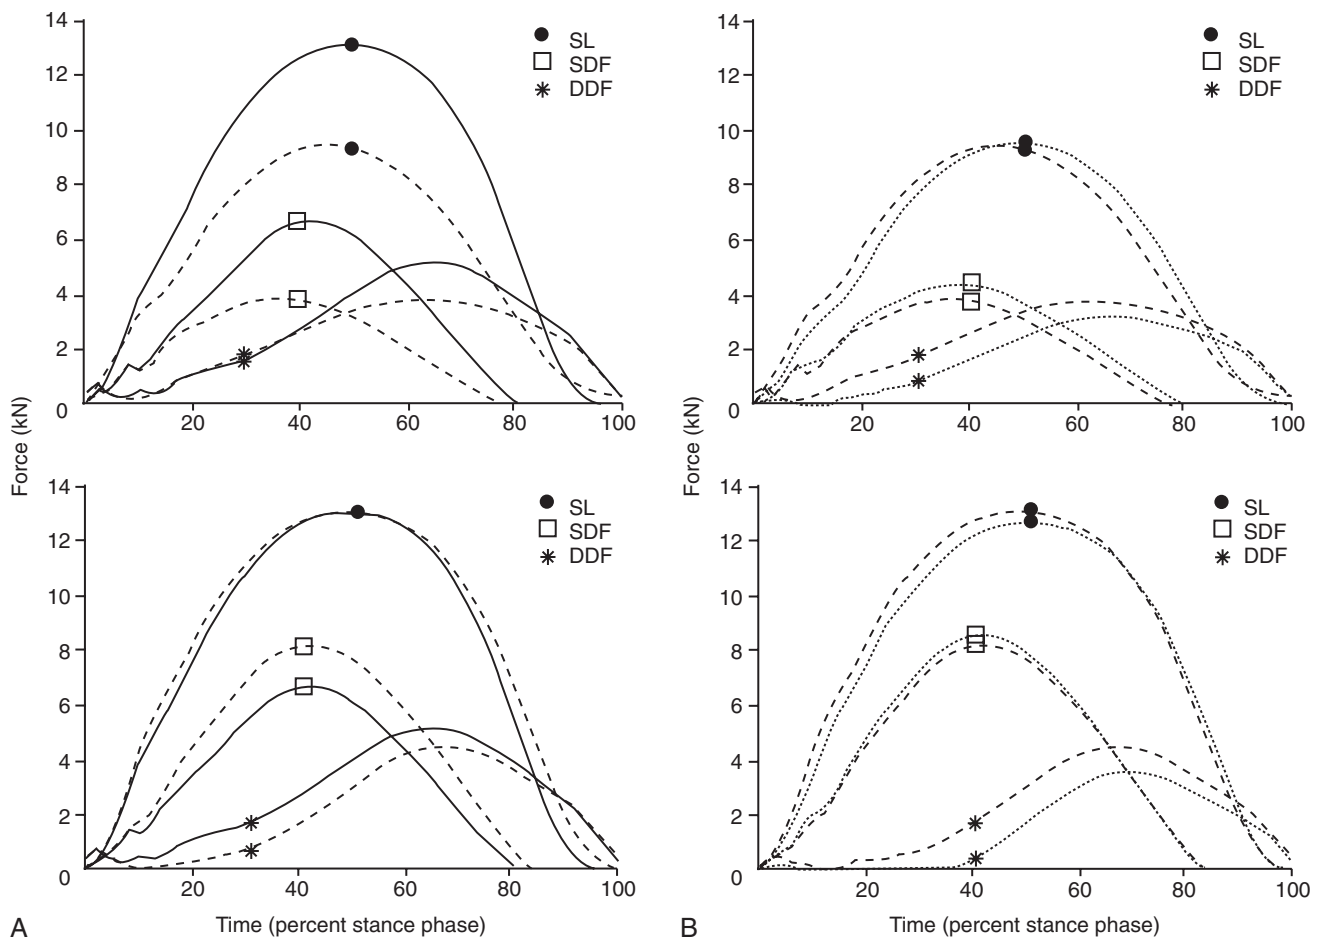

Fig. 26-6 • A, Calculation of mean digital flexor tendon and suspensory ligament (SL) forces in the affected (*top*) and contralateral (*bottom*) forelimb of five trotting horses before (*solid line*) and after (*dashed line*) experimentally induced unilateral superficial digital flexor (SDF) tendonitis. **B,** Calculation of mean digital flexor tendon and SL forces in the affected (*top*) and contralateral (*bottom*) forelimb of five trotting horses with experimentally induced unilateral SDF tendonitis before (*dashed lines*) and after (*dotted lines*) bilateral application of heel wedges. DDF, Deep digital flexor, including accessory ligament of the DDF tendon (ALDDFT); SDF, superficial digital flexor. (From Meershoek LS, Lanovaz JL, Schamhardt HC, Clayton HM: Calculated forelimb digital flexor tendon forces in horses with experimentally induced superficial digital flexor tendinitis and the effects of application of heel wedges, *Am J Vet Res* 63:432, 2002.)

of interest in the development of appropriate training programs. The time course of structural adaptations may be as long as 6 months, and there is the potential for a training program to accumulate damage (because of the exercise volume) before such protective responses occur.

What Happens to the Individual Musculoskeletal Element during Locomotion?

Foot

On contact with the ground the foot must withstand the high forces at impact. During locomotion a forelimb of a horse experiences forces of one half of body weight at a walk, approximately 1 times body weight at a trot, and up to 2.5 times body weight at a canter.

Forces act on the foot primarily in two ways: the GRF acts on the solar surface of the hoof, and tensile forces are applied by the DDFT to its insertion site on the distal phalanx. Forces acting on the foot are transferred between the distal phalanx and the hoof capsule through the laminar junction (see [Figure 26-2](#)). In effect the limb force

is transferred to the distal phalanx, and it is “hung” from the hoof wall by the laminae. This is why in laminitis, with disruption of the dorsal laminae, the dorsal aspect of the distal phalanx drops. Movement of the distal phalanx and deformation of the hoof wall have secondary effects on vascularization, the whole process being termed the *hoof mechanism*.¹⁰

As the hoof capsule comes under load, the main force moves from the palmar or plantar aspect of the hoof dorsally to the toe,²⁴ and the dorsal hoof capsule compresses. The heel expands during the first three quarters of the stance phase and contracts for a short time just before the foot leaves the ground. Heel expansion is greater in trot than in walk, but the timings are similar. Initially the middle phalanx rotates palmar or plantar, causing the heel, frog, and wall to deform under pressure. There is a direct relationship between hoof pressure, particularly in the frog, and heel expansion. However, heel expansion occurs even without ground contact with the frog, and there is no direct pressure from the ground acting on the sole or frog.²⁵

The strain patterns and peak strains of the hoof capsule are complex and are influenced by numerous factors such as gait, hoof shape, shoeing, and surface and pathological conditions.^{10,26,27} Generally strains are lower in walk than in trot and gallop; turning increases the strain on the medial hoof quarter.

Tendons

Accurate measurement of tendon strain is a challenge, especially in live horses, and numerous in vitro and in vivo experiments using a variety of invasive and noninvasive techniques have been conducted to assess tendon strain in horses.

The time-related pattern of loading and the magnitude differ between the digital flexor tendons (see Figure 26-6) and are influenced by surface, conformation, farriery, and pathology.²⁸⁻³² Tendon strain in vivo increases significantly from walk to trot for all digital flexor tendons with the exception of the ALDDFT. The highest strains are experienced by the SL (3.4% at walk, 5.8% at trot), followed by the SDFT (2.2% at walk, 4.2% at trot) and DDFT (1.2%, 1.7%). Strains in the ALDDFT and SL were significantly higher on pavement than on sand, but this was not found for the SDFT and DDFT.³¹ At a gallop, tendon strain can reach 12% to 16%,³³ a level close to failure strain found experimentally (see Figure 68-1), suggesting that a narrow safety margin exists for tendon tissue. A similar distribution of tendon forces has been seen during landing after fences.³⁴ Peak forces were highest in the SL, lower in the SDFT and lowest in the DDFT. Increase in fence height resulted in a substantial increase in SDFT force, whereas forces in the SL increased only slightly, and forces in the DDFT and ALDDFT remained the same. The loading pattern of the digital flexor tendons over time differs between tendons. Force in the SL increases in the first 30% of the stance phase, remains nearly constant at 30% to 70%, and decreases between 70% of stance and foot-off. Force in the DDFT and ALDDFT increases more gradually until its peak at 75% of the stance phase and decreases rapidly thereafter, whereas the SDFT starts loading at 10% of stance and reaches its peak at midstance.

Surface characteristics were related to the incidence of tendon injuries in epidemiological studies^{35,36} and had a significant influence on tendon load in two French trotters: when an all-weather track was compared with a crushed-sand track, the maximum force experienced by the SDFT was higher and was reached earlier in the stance phase on the crushed-sand track than on the all-weather track.³⁷ This corresponds to differences in joint kinematics and foot-surface interaction between the two surfaces. However, more studies are necessary comparing the effect of surfaces on other tendons, bones, and joints before recommendations regarding the most suitable surface can be made.

Bones

The McIII is one of the most commonly fractured bones in racehorses. The stress and strain patterns this bone experiences during locomotion^{33,38,39} are complex, involving compression, shearing, bending, and twisting. Strains exceeding 3000 microstrain have been recorded for the dorsal cortex of the McIII during fast exercise, and the peak compressive strain of this bone at a speed of 16 m/sec was found to be around 4800 microstrain.⁴⁰ These high strain values are thought to stimulate bone modeling, but they can also

cause simultaneous bone damage. However, the peak axial load may be unlikely to cause a fracture in this bone.⁴¹ Axial stress, about 90 N/mm², can be calculated from the measured strain values by taking into account the material properties and average cross-sectional area of the McIII.⁴² This corresponds to about 50% of the ultimate strength.⁴³ It has been shown that the force required to break a bone through bending is only about $\frac{1}{60}$ of the force required to fracture a bone in compression.⁴⁴ Therefore the bending forces are much more likely to cause overload in the McIII. Horizontally directed accelerations and hence the bending forces acting on the McIII are highest during impact, and it has been suggested that any measures interfering with this phase have an effect on the McIII stress.⁴¹ This is supported by the fact that a shorter period of hoof braking after foot contact has been shown to result in higher amplitudes and more rapid oscillation transmitted to the McIII in horses at trot than a longer period of braking.¹⁶

A more detailed description of bone loading is given in Chapter 102.

Joints

Joints are mainly subjected to compressive and shear forces. Direction and magnitude of the force follows the GRF and is influenced by joint angle and conformation of the joints and limb segments. Stress relates to the size and shape of the articular surfaces and therefore differs among joints, but also within a joint. In the metacarpophalangeal (MCP) joint, for example, the stress follows the biphasic GRF pattern during walk at most articular sites, but not the sagittal groove of the proximal phalanx, where stress has been shown to continue to rise after midstance in a majority of horses.⁴⁵ This may contribute to the pathobiology of this specific area. In this joint the stress experienced by the medial part of the joint was significantly higher than the stress acting on the lateral part, which corresponds to the progression of osteoarthritic changes from medial to lateral in this joint.⁴⁶

THE EFFECTS OF CONFORMATION ON EQUINE DISTAL LIMB MECHANICS

The effect of conformation, especially with regard to the relationship among heel height, toe length, and angulation of the phalanges, is commonly discussed by veterinarians and farriers; however, scientific evidence is scarce.

Effect of Toe Length and Angle

Toe length and angle influence the point of force application and hence the moment arm of the GRF around the joints, but also the relative timing of events during the stance phase.

A change in dorsal hoof wall angle of 3.5 degrees over an 8-week shoeing interval resulted in a shifting of the point of force in a dorsal direction and an increase in the moment around the DIP joint, which leads to an increase in stress exerted by the DDFT on the navicular bone.^{47,48} This, however, was lower than expected from predictive calculations, and a compensatory mechanism involving a decrease in extension of the fetlock joint and hence an unloading of the DDFT has been suggested.⁴⁹ An additional compensatory mechanism has been suggested in the hindlimb, where a shift of the point of force laterally has

been observed in late stance, resulting in a shortening of the GRF moment arm around the DIP joint.

When the heel leaves the ground, the body weight acts at the toe, producing a long lever arm on the DIP joint and hence loading the DDFT and the navicular bone. Attempts to reduce the length of this lever arm have been made by fitting a shoe with quarter clips rather than a toe clip and a shoe designed along the lines of the four-point trim (natural balance shoe). Comparing toe clip, quarter clip, and natural balance shoes, pulling the toe back made breakover (heel off to toe off) start earlier and shortened the duration of breakover. The moment arm of the GRF on the DIP joint during breakover was reduced, but because breakover started earlier and hence at a higher GRF, the peak moment and force on the navicular bone were similar with the three shoe types.⁵⁰

Effect of Mediolateral Imbalance

The horse's limb has evolved to function in the sagittal plane, with the GRF vector ideally going through the middle of the limb column to ensure even load distribution in a mediolateral plane. Any out-of-plane conformation results in a change in direction of the GRF vector and its moment arm in relation to the musculoskeletal structure, thus resulting in their uneven loading and hence potential overloading of structures that have low safety factors. Mediolateral imbalance leads to an increase in joint pressure, as well as changes in articular contact area, as demonstrated for the DIP joint after application of medial or lateral wedges.⁵¹ Six-degree lateral or medial wedges resulted in a significant increase in joint pressure and moved the articular contact area toward the elevated side.

One aim of veterinary and farriery intervention is to ensure mediolateral balance through foot trimming or addition of extensions. The effect of such treatments on limb mechanics in sound horses and in horses with OA of the distal hock joints (bone spavin) has been demonstrated. In one study a 6-mm-thick wedge shoe was applied to alter mediolateral foot balance in sound horses of good conformation.²⁴ This wedge moved the PZM toward the elevated side of the foot by about 5 to 10 mm. In a second study a 20-mm-wide lateral extension was applied to the front and separately to the hind feet of sound horses. These extensions had no apparent effect on the position of the PZM. This lack of an effect may demonstrate, however, that "if it ain't broke, you can't fix it." In addition, on soft ground an extension sinks into the ground less than the narrow side of a shoe, creating a wedge effect. In a separate study lateral extensions and trailer shoes were applied to the hind feet of horses with OA of the distal hock joints. These horses attempted to unload the dorsomedial aspect of the distal tarsal joints by redistributing their weight to the plantarolateral aspect of the foot. The lateral extensions (20 mm wide) and trailers (20 mm long on lateral heel) are assumed to act by helping the horse to redistribute its weight in a more comfortable manner either by rotating the foot or by helping the horse bear weight on the lateral side of the foot. An alternative explanation is that the corrective farriery forces the horse to move "normally" and prevents it from unloading the painful tissues and eliciting the repair process. Both extension and trailer shoes had little consistent effect on the position of the PZM through stance or on the clinical lameness score of these

horses, questioning their efficacy as a treatment technique. The Editors question the assumption that pain is focused dorsomedially.

Effect of Heel Height

It is common to change heel height through the application of heel wedges to manage orthopedic disease in horses. The effect of wedges on joint angles, tendon strains, and joint pressure has been the subject of numerous studies and the mechanical effects in the following sections have been described.

Joint Angles, Tendon Strain, and Navicular Force

Heel wedges move the PZM toward the heel and therefore reduce the moment arm of the GRF at the DIP joint and unload the DDFT. The DDFT passes around the navicular bone and exerts a compressive force on the navicular bone. When the DIP joint is flexed, the angle of tendon deviation around the bone is reduced. Angular change and a reduced force in the tendon (because it has shortened) mean that the compressive force on the bone is reduced. Force on the navicular bone is reduced nearly 24% for a 6-degree heel wedge and double that for a 21-degree wedge.¹²

When the heel is unloaded toward the end of stance, there is leverage on the DIP joint, the DDFT, and the navicular bone. With wedge elevation the heel is supported until later in the stride. Vertical force on the limb is reduced when forward displacement occurs, and in turn the moment on the DIP joint should be lower.¹²

These changes are supported by another study in horses with experimentally induced superficial digital flexor (SDF) tendonitis. After bilateral application of 6-degree heel wedges, ALDDFT and DDFT force decreased in both limbs; SDF force stayed the same in the affected limb, but increased in the contralateral limb. These findings suggest that heel wedges may not be beneficial in horses with SDF tendonitis and in fact may contribute to the high secondary injury rate in contralateral forelimbs.³⁴

Experiments using heel wedges have concentrated on the immediate effects of changes in heel height, but there are long-term, repetitive effects and possible compensatory mechanisms that may be important. In a study investigating foot conformation in sound horses there was a strong negative correlation between DDFT strain and navicular bone stress and the ratio of heel and toe height. With elevation of the toe, there is an increase of the GRF moment arm around the DIP joint because of movement of the PZM toward the toe. To counteract the increased extensor moment of the GRF on the DIP joint, the flexor moment has to increase accordingly, which leads to an increase in force in the DDFT. As the DDFT wraps around the navicular bone it exerts a force on the navicular bone, and any increase in DDFT force leads to an increase in the force acting on the navicular bone.¹³ The results of this study support the findings seen after heel wedge application as discussed earlier.

Joint Pressure and Articular Contact

Elevating the heel by 5 degrees has been shown to significantly increase DIP joint pressure, and lowering the heel had the opposite effect. Articular contact area shifted dorsally with elevation of the heel and palmarly when the heel was lowered.⁵¹ An increase in intraarticular

pressure may directly cause pain, and indirectly could change both vascularity of the synovium and cartilage function, triggering a cascade of detrimental events.

Hoof Capsule

The horn of the hoof capsule is arranged in tubules, which is the ideal design to withstand high compressive forces, but which can be highly susceptible to excessive bending forces (comparable to a drinking straw, which is almost impossible to squash by compressing straight from either end but is very easy to bend). The compression strength of a material diminishes rapidly with increasing length, because the buckling limit of a material is proportional to the square of the length. This is why it is a mechanical necessity to maintain tubule length by natural wear or trimming. In horses with a collapsed or underrun heel, the tubules have started to bend once they have grown distal to the distal phalanx. This impairs hoof deformation and associated blood flow to and from the hoof. Application of thin, flexible carbon fiber patches to the medial and lateral sides of the heel is beneficial in maintaining horizontal loading of hoof tubules by preventing bending and restoring hoof deformation and blood flow to more physiological levels.⁵²

EFFECT OF SHOEING

Application of a Shoe

Application of a shoe changes the mass of the distal limb, alters hoof deformation, and influences foot-surface interaction.

A shoe changes the reaction of the distal limb to forces by increasing mass and changing inertia. This has numerous effects, mainly noticeable in the protraction phase of the stride.⁵³ Of more importance with regard to injury are the effects of shoes on the stance phase of the horse, such as a slight increase in loading of the limb, slightly faster rotation of the hoof, less vertical lifting of the hoof,⁵⁴ and an increase of up to 14% in force exerted on the navicular bone by the DDFT.¹² Shod horses also show less heel expansion during stance and more contraction of the heel at the end of stance than unshod horses.²⁵ There is evidence that shoes change ground contact area and load distribution.⁵⁵ These and other mechanisms may account for observed changes in shock-absorbing capabilities observed with shoes,^{56,57} resulting in an increase of load during impact. This increase in impact, however, does not extend much beyond the distal phalanx, and changes between shod and unshod horses are minimal at the fetlock level.¹²

The Influence of Shoe Material

There is anecdotal evidence that some horses are “more comfortable” or “go better” in plastic or rubber shoes. This has been attributed to reduction of “jarring” after impact. Shoe grip varies among shoe types, and various techniques are commonly used to enhance shoe grip, such as studs or high-friction material such as rubber. Time and slide distance of a foot at impact are not significantly altered by shoe application regardless of the material used (steel, plastic, rubber). However, decelerating forces after impact and dynamic friction are significantly lower with plastic shoes compared with rubber or steel shoes.⁵⁸ Horses may

compensate for different shoe-ground interaction by altering gait to maintain a constant slip time and distance.

The Influence of Shoe Type

Egg bar shoes have been shown to have no effect on the force on the navicular bone in sound horses¹² but have had a significant unloading effect in some horses with navicular disease, particularly those with a collapsed heel.⁵⁹ Clinical experience is similar: egg bar shoes may be beneficial in some horses but not others. The mechanism of action is unclear. Egg bar shoes may redistribute load over a larger area of the heel, reinforce or couple the flexible palmar regions of the foot, and/or reduce heel pain. Redistribution of load to make a horse more comfortable also results in a reduced force on the navicular bone. Why egg bar shoes help some horses more than others is unclear but may relate to the exact location of pain, the type of pathology, and/or the degree of heel collapse.

Shoes with toe clips, shoes with quarter clips, and natural balance shoes were compared. Pulling the toe back made breakover (heel off to toe off) start earlier and shortened the duration of breakover. The moment arm of the GRF on the DIP joint during breakover was reduced, but because breakover started earlier and hence at a higher GRF, the peak moment and force on the navicular bone were similar in the three shoe types.⁵⁰

ALTERATIONS IN MECHANICS WITH SPECIFIC ORTHOPEDIC DISORDERS

Changes in kinematics and kinetics are mainly pain induced and rarely pathognomonic in horses. Chapter 22 provides an overview of locomotor changes and compensatory mechanisms associated with lameness in horses and how these can be assessed objectively.

Studies on changes in mechanics with specific orthopedic disorders are rare. These studies are scientifically challenging for a variety of reasons, not the least of which is difficulty in standardizing subjects.

Mechanics of Palmar Foot Pain and Navicular Syndrome

In a study investigating the mechanics of the distal limb in normal horses and horses with palmar foot pain, there was a significant difference in the load distribution through the stride. A combination of force plate analysis, motion analysis, and radiography was used to determine the limb forces, the weight distribution under the foot, the force in the DDFT, and the compressive stress on the navicular bone during the stance phase of trot. These data show that in normal horses the force on the navicular bone rises through stance to a peak at around 85% of stance just before the heel leaves the ground.⁵⁹ This force profile is caused by passive loading of the DDFT via its accessory ligament: as the DIP joint extends in late stance the tendon is stretched, increasing the force in the tendon and hence the compressive force it exerts on the navicular bone. In horses with palmar foot pain, the force on the navicular bone peaks early in stance and again just before the heel leaves the ground. The late peak is similar in magnitude in normal and diseased horses, but the early peak, present

only in horses with navicular disease, results in a much higher loading rate on the bone, which may be responsible for the pathological remodeling observed in horses with the disease.⁸ After palmar digital analgesia the tendon force and hence the force on the navicular bone dropped in early stance and midstance.⁶⁰ The observed changes were thought to be caused by the phenomena discussed in the following paragraphs.

The horse perceives general pain in the navicular or heel region rather than pain specific to the navicular bone. This pain could be the result of a variety of pathologies. The horse compensates for this pain in the heel region by landing toe first. The heel is unloaded at the beginning of stance to reduce concussion. After landing the PZM is moved dorsally, increasing the GRF moment arm on the DIP joint, hence increasing force in the DDFT and increasing the force exerted by the DDFT on the navicular bone. Palmar digital analgesia reverses this response to some extent, and the load on the navicular bone is reduced.⁵⁹ These data suggest there may be a positive feedback mechanism in which navicular region pain elicits a compensatory mechanism that increases the compressive force on the navicular bone. This may explain why some horses with chronic heel pain develop radiological changes in the navicular bones. Whether such an increase in loading would actually cause navicular disease is unproven. This mechanism can also provide an explanation for the reported susceptibility of horses with a broken-back hoof-pastern axis to the development of navicular disease and the tendency of some horses with long-standing navicular disease to develop boxy, upright feet. A horse with collapsed heels will tend to exert a higher force on its navicular bones (because the DDFT is stretched further; see earlier) so it will be more susceptible to develop navicular disease. A long toe increases the moment arm on the DIP joint and thus the force on the navicular bone during toe-first landing and possibly also at breakover. Some horses that are attempting to unload their heels are presumably so successful that they will develop contracted heels and upright feet.

Changes in Mechanics in Horses with Laminitis

A change in foot mechanics is also apparent in horses with laminitis. The laminar junction is weakened, and the normal force transfer from the hoof wall to the distal phalanx via the laminar junction is disrupted. In sound horses the laminae deform elastically under load; in a laminitic horse the laminae change plastically, which, together with detachment of the laminae, results in rotation and/or sinking of the distal phalanx within the hoof capsule, which further disrupts the normal mechanical behavior of the hoof with subsequent consequences to its vascularization.

Laminitic horses land heel first, which is assumed to be to protect the painful dorsal laminae (laminar detachment occurs predominantly in the dorsal region of the foot). Laminar detachment destabilizes the distal phalanx and results in rotation and/or sinking of the distal phalanx, depending on the extent of detachment with respect to the position of the PZM. Rotation occurs when there is weakening of the laminae in the dorsal region, yet the laminae at the heel remain mechanically competent. The distal phalanx pivots about this point so that the toe moves

palmar and distad following the “pull” of the DDFT. Rotation of the distal phalanx causes shortening of the DDFT and reduction of the force in the DDFT. The reduction in DDFT force results in a reduced flexor moment in the DIP joint during stance. Because the moments on the DIP joint must balance, this reduces the extensor moment created by the GRF. This reduction in moment is reflected in the PZM moving toward the heel. The dorsal laminae are unloaded and the proportion of the load transferred through the intact palmar laminae is increased.⁶¹ Rotation can thus be regarded as a self-limiting event, the magnitude (angle) of which depends on the degree of laminar detachment. If extensive laminar detachment occurs, then the forces exerted on the remaining laminae will exceed their mechanical capacity, and the distal phalanx will sink rather than rotate further.

Changes in Mechanics in Horses with Osteoarthritis of the Distal Hock Joints

Horses with OA of the distal hock joints (bone spavin) are described as having a characteristic gait. The gait is characterized by a shortened cranial phase of the stride; the limb is moved medially during the flight phase and then swung laterally just before ground impact (“stabbing”). This gait is believed to be the result of the horse attempting to reduce the load on the painful medial aspect of the tarsus. In a study comparing normal horses and horses with bone spavin and the position of the PZM in the hind feet, the PZM was found to be more plantar and lateral than in normal horses, confirming that they change their gait to unload the painful medial aspect of the tarsus.⁶² The Editors have observed a similar gait associated with many other sources of hindlimb pain and debate the existence of pain on only the dorsomedial aspect of the distal hock joints.

Changes in Mechanics in Horses with Superficial Digital Flexor Tendonitis

In horses with experimentally induced SDF tendonitis, trotting speed slowed and therefore forces decreased. In the affected limb, however, force in the SL decreased more than that in the SDFT and DDFT, thus changing load distribution between the flexor structures (see [Figure 26-6](#)).³⁴ More information about the role of mechanics in the pathobiology of tendon injury is given in Chapter 68.

CONCLUSION

Biomechanics is an ever-changing field, the progress of which is closely linked to the evolution of new techniques and computational power. Horses do not get injured standing still, and musculoskeletal injury is strongly related to exercise. The quantification of locomotor parameters at high speed under field conditions is relatively new and will lead to more insights in the future. The horse's musculoskeletal system is finely tuned by millions of years of evolution, and changes in one structure inevitably lead to changes in others. Understanding the complex interactions among the individual musculoskeletal structures, how they are influenced by the surface, and how these interactions vary among individual horses is a prerequisite to understanding not only the development of musculoskeletal disorders, but also how to best treat them and, even better, how to prevent them.

Chapter 27

The Foot and Shoeing

▣ FOOT BALANCE, CONFORMATION, AND LAMENESS

Andrew H. Parks

Athletic injury usually results from imposition of repetitive stresses that exceed the capacity of the tissues. The magnitude of stresses and hence the likelihood of injury frequently depend on balance and conformation. Therefore balance and conformation are extremely important in maintaining optimal limb function and limiting athletic injury.

Conformation describes shape—in this case, the shape of the distal aspect of the equine limb—and conveys the size and relative proportions of the limb. Balance embraces both the conformation and function of the hoof—conformation because it describes the shape of the hoof, and function because it describes the way the hoof relates to the skeletal structures of the limb and the ground at rest and at exercise. Balance is divided into geometric (static) balance and functional (dynamic) balance.

Balance and conformation are both three-dimensional concepts. Balance usually is divided into three planes: frontal (dorsal), sagittal, and transverse. Balance in the frontal plane is called *mediolateral balance* and in the sagittal plane is called *dorsopalmar (plantar) balance*.

To understand how balance and conformation affect stresses that cause injury, it is necessary to consider the function of the distal limb and then examine how it changes with conformation and balance. Therefore consideration must be given to the musculoskeletal system, the hoof and the ground, and the interfaces. There are some substantial differences between the front and hind feet. Because almost all research and documented clinical observation are related to the front feet, all discussion in this chapter refers to the front feet unless specifically stated otherwise.

The hoof is the interface between the musculoskeletal system and the ground. The hoof functions both as an extension of the distal phalanx, as a lever about the distal interphalangeal (DIP) joint, and as an entity in itself. As part of the integument the hoof behaves differently to the structures of the musculoskeletal system, both in its manner of constant growth and its biomechanical properties. As the hoof capsule is constantly worn at the ground surface, it is replaced by the germinal epithelium of the coronary band and the sole. In nature and in an appropriately trimmed foot, there is an approximate balance between growth and loss of the hoof capsule so that the growth rings are parallel.¹⁻³ The exact mechanism by which hoof growth is regulated is unknown, but several factors are known to influence it: season, inflammation, nutrition, and topical irritants.⁴ Growth of the wall also is inversely related to pressure on the coronary band. Hoof wall growth

proximal to a hoof wall resection or horizontal grooving of the hoof wall appears accelerated, whereas the immediately adjacent hoof wall growth may be retarded.⁵ This effect may be mediated by an effect on the vasculature of the coronary band.

During normal hoof growth the hoof wall migrates distally in relation to the distal phalanx by active separation and reformation of desmosomes as the primary epidermal lamellae move past the secondary epidermal lamellae.⁶ The distal growth of the hoof wall under normal loading patterns is approximately even around the circumference of the hoof, and the position of the coronary band in relation to the distal phalanx is static. However, in response to locally increased and decreased loads within the hoof wall, migration of the coronary band proximally and distally in relation to the distal phalanx is superimposed on the normal pattern of hoof wall migration, suggesting that a whole segment of the wall can displace distally and even proximally by movement within the lamellae.

The stiffness of the hoof wall changes radially, and the outer stratum medium is stiffer than the inner stratum medium but is much less stiff than bone throughout. The stiffness of the hoof wall at the toe and quarters is similar, but the difference in thickness indicates that the quarters are more flexible.⁷ The hoof wall sustains strains greater than bone, but under normal circumstances it operates within its elastic range at a fraction of its yield capacity.⁸ The stiffness of the hoof wall increases with increased strain rate.⁹ The hoof wall is viscoelastic. It responds to a rapidly applied force in an elastic deformation so that it returns to its original form rapidly; however, to a slowly applied force, it deforms in such a manner that when the force is removed, the hoof wall returns to its original form slowly.¹⁰ Because of its physical properties the hoof wall is more fracture resistant than bone,¹¹ but because it is a much less stiff material than bone, it will bend and shear more readily. The biomechanical properties of the soft tissues between the hoof capsule and distal phalanx are less well understood, but the periosteum of the distal phalanx fails before the junction between the epithelial and dermal lamellae.⁸ The lamellar junction is much less stiff than the hoof wall¹²; dorsally the lamellae are oriented perpendicular to the tangent to the hoof wall, but at the quarters they are in a more palmar direction.¹³

FOOT FUNCTION

At Rest

At rest a horse bears approximately 28% to 33% of its body weight on each forelimb. The exact roles of the wall, sole, and frog in weight bearing are undetermined. Weight bearing has traditionally been viewed with a horse on a flat, firm surface so that the weight-bearing surface is the full circumference of the wall and the immediately adjacent sole, although the weight is not evenly distributed around the perimeter of the foot. Studies on feral horses indicate that the toe and quarters are worn so that if the horse stood on a flat, firm surface, the weight would be transmitted through the wall at the heel and the junction of the toe and quarter biaxially, although there is

some variation related to the terrain on which the horse has lived.¹⁴ The dorsal aspect of the toe and midquarters would not bear weight. Domestic horses that were allowed to wear the feet “naturally” at pasture and then stood on different surfaces showed remarkably different loading patterns.¹⁵ When stood on a firm surface, greatest contact was at the medial and lateral aspects of the heel and just medial and lateral to the dorsal aspect of the toe, comparable to feral horses. When stood on sand, the greatest contact was with the central aspect of the sole, and the total contact area was approximately four times greater for horses standing on sand than on a flat, firm surface.

Any part of the ground surface of the foot is potentially weight bearing. Each point of contact that bears weight transmits that force to the ground, although the pressure at each point varies. The sum of all the forces from all points of contact is called the *ground reaction force* (GRF). It is represented as a vector, with a magnitude and direction, and a location or point of force, which is also called the *point of zero moment*. In the stationary horse this force is almost vertical and located slightly medial to the dorsal third of the frog. Therefore the GRF is dorsal to the center of rotation of the DIP joint, with a resultant moment about the joint. This moment is opposed by an opposite moment created by tension in the deep digital flexor tendon (DDFT). The GRF acting through the phalanges creates a moment about the metacarpophalangeal joint that is opposed by tension in the digital flexor tendons and the suspensory ligament (SL).

At Exercise

Stride Phases

The stride is divided into flight and stance phases.¹⁶ The stance phase of the stride is further subdivided into initial contact, impact, support, and breakover. The foot should move in a sagittal plane parallel to the longitudinal axis of the horse.⁵ In an exercising horse the GRF changes in magnitude, point of force, and direction with and within the phases of the stride. The GRF is separated into components in three axes: x-axis (mediolateral), y-axis (dorsopalmar), and z-axis (vertical).

Initial Contact

At a walk, trot, or gallop the initial contact most frequently is heel first,^{17,18} usually the lateral side first, or both sides simultaneously.^{19,20} Medial first landing is uncommon. However, some horses may land flat-footed, and the propensity to do so increases with increasing speed.¹⁹ When the heel does strike first, the foot is flat within 1% to 2% of the stride duration.²¹ Toe-first landing is rare.^{19,21} It has been suggested that the position of the foot at landing is determined by proprioceptive reflexes that optimally orient the position of the distal phalanx before impact, regardless of the length of toe or angle of the foot.²²

Impact Phase

The impact phase is characterized by oscillations in the GRF centered on the heel that last for approximately 50 ms.¹⁶ The oscillations are associated with the highest rate of loading during the stride; thus the greatest likelihood of injury is during the impact phase. The vertical velocity and acceleration are greater in the forelimbs than

in the hindlimbs, which explains the greater concussion and likelihood of lameness in the forelimbs.²¹ Significant damping of the impact oscillations occurs within the hoof, the two most distal phalanges, and the associated articulations.²³⁻²⁵

Support Phase

The support phase extends from the end of impact until the onset of breakover. At a walk the vertical GRF is biphasic, with peaks at either side of the middle of the stride, but at the trot there is a solitary peak approximately halfway through the stride.^{26,27} For most of the stance phase the GRF is slightly medial to the dorsal third of the frog.²⁸ The force is absorbed and energy is stored by the digital flexor tendons and SL as the metacarpophalangeal joint extends²⁹ so that the maximal GRF coincides with maximal extension of the metacarpophalangeal joint.^{17,30} At the walk, forces in the superficial digital flexor tendon (SDFT) and DDFT peak before the peak in the GRF, but the force in the accessory ligament of the DDFT (ALDDFT) peaks during the second half of the stride as the DIP and metacarpophalangeal joints extend.^{31,32} The GRF in the dorsopalmar direction is negative during the first half of the stride as the limb decelerates. The foot continues to slide forward after initial impact until arrested, at 6% of the stride duration in the forelimb³³ and 23% in the hindlimb³⁴ in trotters on a dirt track. The fore foot bounces more on impact, whereas the hind foot slides more.²¹ During the second half of the stride the horizontal GRF becomes positive as the limb accelerates to provide propulsion. The balance of propulsion and retardation is such that the forelimbs contribute more to retardation and the hindlimbs to propulsion.²⁷ Faster gaits create higher GRFs and greater strains in the hoof wall,⁸ DDFT, SDFT, and SL.³⁵ Under in vitro loading conditions, hoof wall strains increase with load as strain field epicenters develop around the circumference of the hoof, at the junction of the middle and distal thirds of the hoof, regardless of load.³⁶

The distal phalanx is loaded during the stance phase. It was initially thought that the palmar processes rotate palmarly during loading,³⁷ but recent finite element analysis indicates that the toe rotates distally and that the palmar processes move proximally; the findings of the finite element analysis, though not yet verified in vivo, are consistent with observations of hoof wall deformation and strains.³⁸ The sole flattens and spreads as the heel expands,^{2,39} more so distally than proximally.⁸ At the same time, the dorsal hoof wall flattens and rotates palmarly to parallel movement of the distal phalanx. Frog contact with the ground during exercise appears to be variable.^{25,39} The role of frog pressure in hoof expansion is undetermined; there is evidence that indicates it is not involved, yet other evidence suggests that frog pressure is not the sole determinant of hoof expansion but may enhance it.^{25,40} Either way, the frog must function as an effective expansion point to permit movement of the sole ventrally and the heel abaxially. It is hypothesized that the digital cushion, in conjunction with the cartilages of the foot, participates in dissipating energy during impact through a hydrodynamic mechanism.^{41,42} The DIP joint passively flexes⁴³ and the metacarpophalangeal joint extends. During the second half of the stride the DIP joint extends⁴³ and the tension in the ALDDFT increases.³² Tension in the collateral

sesamoidean and distal sesamoidean impar ligaments also increases,⁴³ and pressure on the navicular bone increases.⁴⁴ The metacarpophalangeal joint flexes. The point of action of the GRF moves toward the toe toward the end of the stance phase.¹⁶

Breakover Phase

Breakover begins when the heel starts to lift off the ground and ends when the toe leaves the ground. The point of breakover is the most dorsal part of the hoof or shoe in contact with the ground as the heel begins to lift off the ground. From the instant the heel and sole have left the ground, the GRF is concentrated at the toe. Tension in the ALDDFT peaks,³¹ and increased strain in the dorsal hoof wall⁸ causes the distance between the medial and lateral aspects of the heel to be narrower than at rest. The horizontal forces between the ground and the hoof at the toe during the latter part of the stance phase and breakover are associated with the final stages of propulsion.

Flight Phase

The flight phase begins at maximal retraction of the limb and the foot reaches maximal height soon thereafter. A second peak in height occurs just before maximal protraction. The limb retracts slightly before impact to decelerate the limb as the distal phalanx is optimally aligned for impact. The deceleration of the forward movement of the foot is important in reducing the stresses of impact.⁴⁵ The stresses on the distal aspect of the limb during the flight phase are low, because the distal joints flex and extend passively following movement of the upper limb during protraction.¹⁶

Stride Characteristics

The time and motion characteristics of the stride are important in determining the animation qualities of the gait and the speed of the horse. Higher movement of the foot and greater flexion and extension of the joints represent greater animation. Long retraction with a high starting point is considered desirable, and longer strides are associated with greater speed. Maximum stride frequency is inversely related to speed index.⁴⁶⁻⁴⁸

The ground surface affects the angle of the hoof to the ground during the stride, the duration of the stride, and the absorption of impact energy. On a flat, firm surface the plane of the hoof is the same as that of the ground, but on a surface such as sand, the angle of the hoof with the ground increases gradually during the stance phase of the stride.³⁵ This rotates the plane of the sole so that it is more perpendicular to the vector of the GRF, which appears to aid traction and propulsion. Ground footing has been divided into three types: dense hard surfaces, surfaces with friction damping such as sand, and structural damping surfaces such as wood chips.⁴⁹ Friction damping occurs through displacement of small particles, whereas structural damping occurs through viscoelasticity of the particles. The duration of impact oscillations is related to the hardness of the surface. Harder surfaces are associated with a longer duration of impact oscillations than soft surfaces and less energy absorption.⁵⁰ A loose cushion on the surface reduces the peak impact force.⁵¹ Racetracks with a hard surface result in faster race times, but horses are more likely to sustain injury associated with the increased energy of

impact.⁵¹ Ground footing also affects stride and swing duration, which are both longer on an elastic, softer surface than a hard, firm surface.⁵² At a walk, strain in the DDFT and ALDDFT is lower on sand than on a hard, flat surface,³⁵ such that it resembles the effect of a heel wedge.

OPTIMUM BALANCE AND CONFORMATION

Optimum function should intuitively demand optimum conformation and balance. Practitioners have inherited many empirical notions that often are based on what types of conformation and balance do not work and cause problems. Generally these ideas predate modern motion analysis and therefore relate to conformation and static balance. Modern techniques that allow dynamic evaluation of function have supplemented and sometimes contradicted the geometric approach.

Static Balance and Conformation

Viewed from the lateral aspect, the foot-pastern axis should be straight; that is, the dorsal hoof wall should be parallel to the dorsal surface of the pastern, and the angle of the heel should approximate that of the dorsal hoof wall (Figure 27-1). The angle of the dorsal hoof wall and the foot-pastern axis to the ground is variable, but it frequently is cited as 50 to 54 degrees in forelimbs and approximately 3 degrees steeper in hindlimbs.⁵³ Other studies report higher or lower means and variable relationship between the angles of the dorsal hoof wall of the forelimbs and hindlimbs.^{54,55} In domestic horses the length of the hoof wall has been approximately linked to the weight of the horse (7.6 cm for 360 to 400 kg; 8.25 cm for 430 to 480 kg; 8.9 cm for 520 to 570 kg).⁵³ In feral horses the toe length ranges from 6.7 to 8.9 cm^{14,54} but is independent of weight.⁵⁴ In domestic horses with either trimmed or shod hooves, the length of the heel should be approximately one third that of the toe,^{2,55} but in feral horses it varies with

Fig. 27-1 • Traditional guidelines defining normal dorsopalmar static or geometric balance. The dorsal hoof wall should be parallel to the dorsal aspect of the pastern and to the hoof wall at the heel. A line bisecting the third metacarpal bone should reach the ground at the weight-bearing parts of the heel.

the terrain.¹⁴ An imaginary line that bisects the third metacarpal bone (McIII) should intersect the ground at the most palmar aspect of the weight-bearing surface of the heel.^{56,57}

On a lateromedial radiographic image the dorsal hoof wall should be 14 to 20 mm thick depending on breed⁵⁸⁻⁶⁰ and parallel to the dorsal surface of the distal phalanx. The angle made by the distal solar border of the distal phalanx with the ground ranges from 2 to 10 degrees.^{58,60,61} The center of rotation of the DIP joint is palmar to the center of the ground surface of the foot. Viewed from the dorsal aspect, a line bisecting the metacarpal region should bisect the phalanges and foot, so that the foot is approximately symmetrical, including the mass of foot on either side of the line and the heights and angles of the walls.^{1,3,57,61} The medial quarter is frequently steeper so that the medial wall is shorter than the lateral wall.^{2,62,63} A line drawn between any two comparable points on the coronary band should be parallel to the ground, and a vertical line bisecting the McIII should be perpendicular to a line drawn across the coronary band or the ground surface of the foot⁶² (Figure 27-2).

On a dorsopalmar radiographic image the center of the DIP joint should be centered over the ground surface of the foot. Ideally, the articular surface of the distal phalanx should be parallel to the ground, but it is more important that the interphalangeal joint spaces be even.

Viewed from the ground surface the width and length of the hoof capsule of the fore foot should be approximately equal, although the hoof capsule may be slightly wider than it is long.^{54,62} The hind foot is invariably slightly longer than it is wide. The point of breakover is best assessed from the ground surface and should be located near the center of the toe. Dynamic studies of the location of the GRF during breakover show that it deviates laterally

during breakover, returning toward the dorsopalmar axis of the limb before the foot leaves the ground²⁰; this suggests that breakover normally occurs lateral to the dorsopalmar axis of the foot. The ideal location for breakover in the dorsopalmar axis is disputed. In a traditionally trimmed and shod horse, breakover is positioned where the line of the dorsal hoof wall intersects the ground, although it may ideally be located more palmarly. With the position of the hoof wall used as the reference point, breakover is between the dorsal margin of the hoof and the white line.⁶⁴ Alternatively, breakover is 2.5 to 3.8 cm dorsal to the apex of the frog or 0.6 cm dorsal to the dorsal margin of the distal phalanx.^{14,65} The relationship of the longitudinal axis of the frog to the underlying distal phalanx is relatively constant compared with the rest of the ground surface of the hoof. The medial and lateral aspects of the ground surface of the foot are symmetrical about the central axis of the frog,^{3,57,64} although slight asymmetry, the lateral sole being about 5% wider than the medial sole, may be beneficial.⁶² The latter is compatible with an even coronary band and a steeper medial wall. The size of the foot should be proportional to the weight of the horse.^{54,55} The sole should be concave. The frog width should be at least 50% to 67% of frog length,^{55,62} and the weight-bearing surface of the heel should coincide with the widest part of the frog.⁵⁵

Dynamic Balance

Current definitions of dynamic balance describe the placement of the foot at initial impact. Traditionally, the foot is said to be in dynamic mediolateral balance when the medial and lateral aspects of the heel contact the ground simultaneously^{3,63} and breakover occurs near the center of the toe.⁶³ The foot is said to be in dynamic dorsopalmar balance when either the heel lands slightly before the toe or the toe and the heel contact simultaneously.³ However, both these observations are a function of observation frequency. The fewer observations made per unit time, the more likely the foot is to appear in balance. The more frequently the observations are made, the less likely the foot is to appear in dynamic balance. With increased frequency of observation, it appears that the lateral aspect of the heel or quarter commonly lands first or that the lateral and medial aspects of the heel land simultaneously, but that medial first landing is rare.^{19,20} It is likely that the scope of dynamic balance will expand in the future to incorporate the magnitude, location, and direction of the GRF; distribution of stresses within the hoof capsule during the stride; and dynamics of breakover.

Fig. 27-2 • Traditional guidelines defining normal mediolateral static or geometric balance. A single line should bisect the metacarpal region and phalanges. A line drawn across any two comparable points on the coronary band, or on the weight-bearing surface of the foot, should be perpendicular to the axis of the metacarpal region.

IMBALANCE AND POOR CONFORMATION

Balance and conformation cannot be considered in isolation, because poor conformation predisposes a horse to developing imbalance, and an imbalanced foot may cause a horse to stand as if it had poor conformation.¹ The effects of imbalance have been examined by experimentally inducing imbalance and by clinical observation. To understand the effects of imbalance it is simplest to consider the consequences of deliberately unbalancing the foot. Poor conformation cannot be readily altered under experimental conditions, and its effects must be assessed by comparison between horses with different conformations.

Mediolateral Imbalance

Mediolateral imbalance is caused by either poor trimming of a horse with good conformation or poor conformation causing excessive stress on one side of the foot so that it grows more slowly than the other side. Inappropriate shoe placement can promote imbalance. If a shoe is set too much to one side or the other, or if the shoe is rotated so that the shoe covers less of the medial or lateral aspects of one heel than the other, it alters the mediolateral stress on the hoof capsule.⁶⁶ A single heel calk causes elevation of one side of the foot; the foot tilts and rotates and may contribute to interference.⁶⁶

Mediolateral imbalance can be induced by applying a wedge pad to elevate the medial or lateral side of a foot or trimming a foot unevenly. The coronary band is no longer parallel to the ground or perpendicular to the sagittal axis of the limb. The horn tubules of the dorsal hoof wall are no longer oriented in the sagittal plane. Dorsopalmar radiographic images demonstrate that the DIP joint space is narrower on the side of hoof elevation, and the middle phalanx slides to the lower side.⁴³ In addition, the condyle of the middle phalanx on the elevated side of the foot moves palmarly, in effect causing the distal phalanx to rotate on the middle phalanx so that the dorsal margin of the distal phalanx rotates away from the elevated side⁴³ (Figure 27-3), but the horse has the appearance of being toed toward the elevated side.¹

The GRF shifts toward the elevated wall.⁶⁷ In foals, compressive strains were immediately increased in the lateral cortex of the McIII and decreased in the medial cortex by elevation of the lateral wall with a wedge.⁶⁸

The immediate dynamic effects of mediolateral imbalance result in a greater frequency of mediolateral asymmetrical footfall, the lengthened side landing first.¹⁹ The location of the GRF displaces abaxially toward the lengthened side of the foot.^{19,69,70}

Prolonged mediolateral imbalance affects the relationship between the hoof capsule and the distal phalanx, causes distortion of the hoof capsule, and alters hoof wall growth.⁷¹ If a foot is trimmed unevenly, so that one wall is longer than the other, the longer wall grows more slowly than the shorter wall. The longer wall develops a flare, and the shorter wall becomes underrun.^{1,71} In more severely affected horses the coronary band bulges abaxially to create a lip at the proximal margin of the hoof wall on the elongated side. The horse breaks over on the shorter side of the toe. It is my impression that the solar margin of the distal phalanx partially realigns with the ground surface, either because the wall actually migrates proximally or because distal movement of the hoof wall is inhibited, resulting in a net proximal displacement of the coronary band in relation to the distal phalanx. Ultimately, prolonged mediolateral imbalance causes remodeling of the phalanges because of redistributed stresses according to Wolff's law.

Rotational deformities and angular deformities may mimic each other. In most rotational deformities, it appears as if the metacarpophalangeal joint is the most proximal joint to be rotated, but it is not uncommon for the carpus to appear rotated. With rotational deformities, the McIII is vertical and the observer can rotate around the limb until the metacarpal and phalangeal axes are correctly aligned unless the rotation occurs within the phalangeal axis. In

Fig. 27-3 • Mediolateral imbalance causes misalignment of the articular surfaces and rotation of phalanges in relation to each other. Deliberate elevation of one wall causes the articular surface of the distal phalanx to tilt, but it does not tilt as much as the ground surface of the foot, indicating that there is accommodation within the viscoelastic structures of the foot. The distal articular surface of the middle phalanx is displaced from the elevated side of the foot. The inset in the upper right corner shows that the joint space (outlined in black) on the elevated side of the foot (*left*) is narrower than on the lower side (*right*) of the foot, caused by compression of the distal interphalangeal joint surface on the left side.

horses with angular deformities that occur proximal to the fetlock, including base-wide or base-narrow conformation, the McIII may not be vertical and there may not be a viewpoint from which the metacarpal and phalangeal axes are correctly aligned.

Rotational deformities, such as toe-in and toe-out conformation, alter the position of the ground surface of the foot in relation to the midsagittal vertical axis of the limb. Toe-in conformation causes the foot to wing out during the flight phase of the stride,¹ and if the limb does not deviate from a vertical axis, the foot lands on the lateral heel quarter and breaks over at the lateral toe. Toe-out conformation causes the foot to wing in during the flight phase of the stride. The foot lands most frequently on the lateral heel quarter, as with toe-in conformation (see Figure 4-13). Breakover is less consistently directed than breakover in horses with toe-in conformation. Angular deformities, including base-wide and base-narrow conformation, and varus and valgus deformities also alter the position of the ground surface of the foot in relation to the ideal vertical axis of the limb. If an angular deformity (e.g., varus) is severe enough that the distal aspect of the wall at the quarter is axially directed, it will become underrun. Rotational and angular deformities may occur in combination, complicating the picture.

Dorsopalmar Imbalance

Dorsopalmar imbalance has several causes. A broken-back foot-pastern axis may follow poor trimming, either leaving the toe too long or trimming the heel too short. A shod horse wears its heels against the shoe whereas the toe wears very little, so the hoof angle changes up to 3 degrees over 8 weeks.^{2,72} This change must be allowed for by trimming the toe slightly more than the heel, because even trimming around the foot causes a gradual decrease in the hoof angle.³ Using too small a shoe or leaving a shoe on too long causes the palmar ground contact to move dorsally, imposing greater stresses on the heel, which then is prone to collapse.^{63,66} Toe grabs and heel calks alter the foot axis and concentrate stress.⁶⁶ Thoroughbred horses may have a genetic predisposition for a broken-back foot-pastern axis; galloping causes the angle of the dorsal hoof wall to decrease, and removing the horse from training causes it to increase.⁷³

At rest, elevation of the heel causes the DIP and pastern joints to flex and the metacarpophalangeal joint to extend.^{74,75} The effect is greatest at the DIP joint.^{74,75} In addition, elevation of the heel increases DIP joint pressure and localizes the contact dorsally between the middle and distal phalanges; toe elevation localizes articular contact to the palmar aspect of the joint.⁷⁶ In vitro, elevation of the heel with a wedge decreases the strain in the DDFT, the extensor branches of the SL, and the medial hoof wall⁷⁷ and decreases the moment about the center of rotation of the DIP joint.⁷⁸ The horizontal distance between the center of rotation of the DIP joint and the toe decreases with heel elevation. In addition, the horizontal distance between the toe and an imaginary vertical line bisecting the McIII dropped to the ground is decreased. The clinical consequence of heel elevation is decreased heel growth indicative of increased stress within the wall of the heel.

Lowering the heel or raising or lengthening the toe to create an acute hoof angle or long toe increases the likelihood of toe-first landing.^{19,22} Heel wedges increase the

maximum flexion of the DIP joint during the support phase of the stride and decrease the maximal extension of the DIP joint during breakover.⁷⁹ Elevating the heel increases the likelihood of heel-first landing.¹⁹ The overall impulse (force \times time) on the foot is least when the foot-pastern axis is straight, indicating that a straight foot-pastern axis is least injurious to the foot.¹⁹ At a walk, elevating the heel decreases the strain in the DDFT and its AL^{32,78} with little effect on the SDFT and SL. The decreased strain in the DDFT is reflected in decreased pressure on the navicular bone.⁴⁴ Elevating the toe results in a marked increase in strain in the ALDDFT and a lesser increase in strain in the DDFT at the end of the stride as a result of increased extension of the DIP joint.³² Strains in the SDFT and SL are either reduced or unchanged.^{32,78} Horses with small hoof wall angulation have a prolonged breakover, but the length of stride, duration of the stance, and swing phases are unchanged.^{19,22} When hind feet are trimmed with more acute hoof wall angulation, breakover is delayed but the timing of impact is unchanged as normal coordination is restored during the swing phase of the stride. There is an increase in overreach distance, the distance between the print of the front foot and the landing point of the hind foot.⁸⁰ Heel wedges delay the dorsal shift in the GRF and decrease the maximum torque about the DIP joint during the second half of the stride. Toe wedges have an opposite effect.^{32,70} However, neither toe nor heel wedges alter the dorsopalmar position of the point of force during mid-stance of the stride, indicating that the heel is not unloaded. Both toe and heel wedges cause medial displacement of the point of force.⁷⁰ Increasing the length of the toe prolongs breakover but does not alter stride length; however, it increases maximal flexion of the metacarpophalangeal joint during the swing phase.^{81,82}

The position of breakover in the sagittal plane appears to influence the angle of the dorsal hoof wall and the distal phalanx. Moving the point of breakover palmarly from the most dorsal margin of the hoof wall increases the angle of the dorsal hoof wall and the ground and increases the alignment between the middle and distal phalanges.^{65,83} Whether this effect is related to the biomechanical properties of the dorsal hoof wall or relief of pain within the foot is undetermined. The effect of increased hoof angle on hoof wall strain is inconsistent. In an in vitro model, hoof wall strain did not change with increased hoof wall angle.⁷⁷ In contrast, in an in vivo experiment, increased hoof wall angle increased hoof wall strain more at the lateral quarter than at the toe and not at all at the medial quarter.⁸⁴

The effect of pastern length and the angle of the foot-pastern axis are less well established. The angle of the hoof-pastern axis to the ground is a feature of a horse's conformation. It cannot be changed experimentally, but comparing horses with different conformations shows that the point of force in horses with a small hoof-pastern axis angle is more palmarly positioned than in horses with a larger axis angle.²⁸

Prolonged dorsopalmar imbalance also has delayed effects because of the nature and growth of the hoof capsule. In barefoot horses, trimming the feet to reduce the dorsal wall angle by leaving the toe long causes the ground surface of the foot and the frog to become narrower, and the shape of the ground surface tends to skew away from a circular shape.⁸⁵ As might be expected, the heel appears

to grow much faster, but curiously, the wall at the toe also grows faster. Neither the area of the sole nor the length of the frog change. Interestingly, when the foot is trimmed with a short toe to increase the dorsal wall angle, neither the width nor the shape of the frog or hoof changes.⁸⁵ Clinically, the same appears to occur in shod horses. In horses with extremely long toes the foot becomes "hoof bound." The heel of long-toed horses is predisposed to become underrun because the heel bends dorsally. Both of these phenomena are seen in Tennessee Walking Horses or American Saddlebreds intentionally shod with long hooves.

Other Forms of Imbalance

Many horses with imbalanced feet have a combination of mediolateral and dorsopalmar imbalance. For example, a foot with a sheared heel has one bulb of a heel longer than the other, which is frequently associated with a flared toe quarter on the opposite side of the foot.⁸⁶ Diagonal imbalance has been described dynamically. The hoof lands on one corner of the hoof capsule and then loads the diagonal corner, with consequent distortion of normal hoof capsule shape and alignment with the rest of the distal limb.⁸⁷ Other local deformations of the hoof wall occur, either uniaxially or symmetrically, that do not fit the classical description.

IMBALANCE AND POOR CONFORMATION AS A CAUSE OF LAMENESS

Poor conformation and imbalance of the distal aspect of the limb are common, as is pain causing lameness that can be isolated to the distal aspect of the limb. However, demonstrating the correlation is not always straightforward. In some horses an obvious disease process and obvious imbalance coexist, and when the imbalance is treated the lameness improves. In other lame horses, imbalance is evident with no other clinical, radiological, or scintigraphic evidence of disease, and treating imbalance also improves the lameness. In yet other lame horses, there is evidence of imbalance, with or without other evidence of disease, but treating the imbalance does not improve the lameness. To my knowledge, only one study thoroughly investigated the effects of hoof balance on injury. The odds of catastrophic musculoskeletal injury and suspensory apparatus failure were lower when the lateral sole area was greater than the medial sole area.⁶² Suspensory apparatus failure was more likely the greater the difference between the angles of the dorsal hoof wall and the heels. McIII condylar fractures were less likely with a steeper toe angle.

Mediolateral imbalance is associated with a shift in the point of force of the GRF, distortion of the hoof capsule, induced asymmetry of the articulations of the distal limb, and rotation of the DIP joint. With increased compressive stresses the following problems are clinically presumed to follow imbalance: subsolar bruising, hemorrhage in the white line from laminar tearing, pain from shearing heel bulbs, quarter or heel cracks, thrush in narrow frogs, pedal osteitis, fractures of the palmar process of the distal phalanx, sidebone, synovitis, osteoarthritis, and more proximal fractures.^{1,57,63,66}

The effects of dorsopalmar imbalance should be separated into the effects of broken-forward and broken-back foot-pastern axes. A broken-back foot-pastern axis increases

the load on the palmar aspect of the foot during weight bearing and increases the stresses in the toe at breakover. It causes hyperextension of the DIP joint and increases the tension in DDFT and pressure on the navicular bone. Therefore it can be expected to be associated with heel bruising, lamellar tearing at the toe, osteitis of the palmar processes of the distal phalanx, navicular disease, tendonopathy at the insertion of the DDFT, and more proximal injuries of the tendons or suspensory apparatus.^{3,57,63,66} In the hindlimb a broken-back foot-pastern axis appears to be associated with tarsal and back pain.

A broken-forward foot-pastern axis (upright) appears to be less pernicious.^{3,57} It increases the load on the dorsal half of the foot and decreases tension in the DDFT. The principal findings are subsolar bruising distal to the dorsal distal margin of the distal phalanx and subsequent osteitis of the distal phalanx.⁵⁷

An upright foot-pastern axis has traditionally been considered to predispose toward concussive injuries of the weight-bearing structures in the limb, whereas a foot-pastern axis with an acute angle to the ground predisposes toward strains and sprains of the flexor apparatus. Similarly, a long pastern has been considered to predispose toward strains and sprains.

Any angular deformity located more proximal in the limb that increases the mediolateral symmetrical loading of the foot can be expected to have effects similar to mediolateral imbalance. Rotational deformities do not seem to be a frequent cause of problems. Toe-out conformation is more likely to cause interference, but anecdotally, toe-in conformation is considered more likely to cause lameness.

Undoubtedly, technological advances in diagnostic imaging and pain localization will help identify other combinations of disease and structure. Epidemiological studies will confirm the relationships between the different features of poor conformation and imbalance and disease.

CLINICAL IDENTIFICATION OF HOOF IMBALANCE

The horse must be observed while it is standing squarely to assess each limb in relation to the whole and in motion on a flat, level surface. Each foot must be examined on and off the ground.

Mediolateral Imbalance

Visual inspection should note the position of the entire limbs to identify angular or rotational deviations more proximally in the limb that may have repercussions for the foot (Figure 27-4). Visual inspection of the foot on the ground should note rotational deformities of the metacarpophalangeal joint and placement of the foot in relation to the sagittal axis of the limb. The hoof capsule should be inspected closely for asymmetry of the coronary band. This is frequently a strictly visual inspection, but graphing the height of corresponding medial and lateral points on the coronary band provides objectivity that can highlight an imbalance and provide a record for future comparison.^{55,88} The medial and lateral walls should be inspected for flares and evidence of an underrun heel, lipping at the coronary band, and even spacing between the growth rings.

The ground surface of the foot reflects changes elsewhere in the hoof capsule. The foot should be approximately symmetrical about the center of the frog. In

Fig. 27-4 • Feet of a yearling with bilateral mediolateral static imbalance. The lateral wall of both front feet reaches higher than the medial wall so that the lateral coronary band is higher than the medial coronary band; consequently, the dorsal aspect of the coronary band is sloping distally and medially. The growth rings are also tilted in the same direction as the coronary band. The imbalance creates the impression that the pastern is no longer centered in the foot but is displaced laterally.

mediolateral imbalance, the sole may appear wider on the side with a flare in the wall and narrower on the side with an underrun wall. Dorsal displacement of the ground surface of one heel bulb in relation to the other accompanies proximal displacement of the coronary band at the heel commonly associated with sheared heel. Wear of the shoe or wall at the toe indicates the point of breakover. Alternatively, the breakover point may be identified by lifting the antebrachium cranially, allowing the metacarpal region and pastern to hang passively, and then lowering the foot; the point of breakover is the first part of the foot to touch the ground⁵⁷; however, this assumes that breakover occurs at the same point regardless of the gait and speed of the horse. Breakover frequently occurs slightly lateral to the center of the toe in horses with normal balance, but any marked asymmetry in breakover may indicate mediolateral imbalance. It also may follow angular or rotational deformities of the limb. Asymmetrical bruising adjacent to the wall at either quarter may signify excessive concussion caused by mediolateral imbalance or laminar tearing in a wall with a flare.

Examination of the distal aspect of the limb for rotational or angular conformation by viewing the limb on the ground from the dorsal aspect may be misleading because it is influenced by weight bearing. The ground surface of the foot automatically aligns with the surface of the ground regardless of the relative lengths of the medial and lateral hoof wall. This causes secondary rotation within the phalangeal axis. To circumvent this rotation, to find the point of breakover the limb can be examined off the ground by lifting the limb by holding it forward from under the carpus; the angulation or rotation within the distal limb is observed by sighting down the metacarpal region, pastern, and hoof.⁵⁷

The traditional way to assess mediolateral balance is to sight across the ground surface of the foot with the leg off

the ground, holding the proximal metacarpal region and allowing the digit to hang downward in the sagittal plane with the metacarpophalangeal and interphalangeal joints in passive extension. A line drawn across any two corresponding points on the circumference of the ground surface of the wall should be perpendicular to the axis of the limb as judged by the metacarpal region. If the limb is perfectly symmetrical about the axis of the limb, without angular or rotational deformities, and the observer is directly above the limb, this technique is probably satisfactory within the limits of the observer. I question the accuracy of this technique because most distal limbs are not symmetrical but have at least some element of rotation about the metacarpophalangeal joint. A smaller number of horses have true angular deformities at the metacarpophalangeal joint. For reliability, there must be consistency in the extension of the metacarpophalangeal joint and in the position of the observer. T-squares have been used to improve the reliability of this observation,^{4,57} but misalignment of the T-square with the axis of the metacarpal region decreases accuracy.

Dynamic mediolateral balance is assessed by observing the horse from in front and from behind at a walk and at a trot. Because the degree to which symmetry of landing can be detected is a function of the frequency of observation and speed of the horse, only more severe imbalances can be detected at a trot compared with a walk, and more subtle differences in timing remain undetected unless a video recorder or more sophisticated measuring equipment is used. During the flight phase of the stride, movement of the foot, phalangeal axis, and more proximal limb is observed in relation to the plane of travel to correlate with previously noted rotational and angular deformities.

A dorsopalmar radiograph is the only means to assess the relationship between the hoof capsule and the phalanges (Figure 27-5). Overt imbalance can be detected on

Fig. 27-5 • Radiological assessment of balance has been described by Caudron and colleagues.⁸⁹ **A**, Rotation between the phalanges is indicated when a line bisecting the distal phalanx is not perpendicular to the articular surface of the distal phalanx. **B**, A tilt in the axis of the hoof capsule is determined radiologically when a midsagittally placed wire marker is not perpendicular to the ground surface of the foot. **C**, Tilting of the distal phalanx is evident when a line drawn perpendicular to a line drawn across the articular surface of the distal phalanx is not perpendicular to the ground. All measurements presuppose that the radiographic beam bisects the foot (the dorsal wire marker bisects the apical process of the distal phalanx and the central sulcus).

routine dorsopalmar radiographs, but detection of more subtle changes requires strict technique because apparent radiological imbalance can be readily induced artificially. Both feet must be weighted equally, because unilateral weight bearing induces mediolateral asymmetry and rotation of the interphalangeal joints.⁴³ The foot must be allowed to assume its natural orientation to the rest of the limb, most reliably achieved if it is placed on a swiveling block. Deformation of the hoof capsule may be induced by rotation within the limb, which may change the angulation of the distal phalanx with the ground.⁸⁹ The metacarpal region must be within 10 degrees of vertical in the frontal (dorsal) plane. The x-ray beam must be horizontal and centered on the midsagittal plane so that a wire marker centered on the dorsal hoof wall bisects the central sulcus of the frog on the radiographs. Neither toe-in nor toe-out conformation alters the radiological measurements of mediolateral balance if assessed in this manner.^{90,91} Interpretation of balance from dorsopalmar radiographs is usually based on examining either the relationship between the articular surface of the distal phalanx and the ground, which are ideally parallel, or the symmetry of the phalangeal joints, which should be of even width medially and laterally. When these appear to be in disagreement, I consider joint asymmetry to be more important because it is difficult to envisage a circumstance under which it is not harmful. In addition, interpretation of imbalance is more complex in horses in which the imbalance is chronic because the imbalance is associated with compensatory changes in hoof wall growth and also appears to be associated with movement of the hoof capsule in relation to the distal phalanx.

Although mediolateral imbalance can unquestionably cause lameness, the hoof capsule is not necessarily or even likely to be the site of pain that is associated with lameness. Rather the pain is associated with the effects of imbalance,

that is, stress on the deeper structures of the hoof and the musculoskeletal structures of the distal aspect of the limb. Therefore it is not surprising that the lameness may improve with perineural or intraarticular analgesia of the distal aspect of the limb in a similar manner to osteoarthritis of the DIP joint or navicular disease.

Dorsopalmar Imbalance

The limb is examined for angulation at the carpus and metacarpophalangeal joint. The foot-pastern axis is visually inspected to determine whether the axis is straight or broken forward or back. This method provides only a rough guide. Visual examination can be improved by using a gauge, one limb of which is aligned with the pastern and one with the dorsal hoof wall. However, deciding exactly what landmarks to use on the pastern for alignment introduces irregularity. In addition, the axis changes as the horse shifts its weight or posture. Similarly, concavity of the dorsal hoof wall in the sagittal plane raises the issue of with what to align the pastern. If the dorsal hoof wall is concave, usually the top third of the hoof wall is the most closely aligned to the dorsal surface of the distal phalanx.

The length of the toe from the proximal aspect of the coronary band to the ground surface in the midsagittal plane of the hoof is readily measured with a tape and compared against reference values or previous measurements for the same horse. This information is greatly underused. The length and angle of the heel also are evaluated. Only the wall at the heel distal to the bulb should be evaluated, because inclusion of the heel bulb causes the angle to be underestimated. A heel that is angled more acutely to the ground than the dorsal hoof wall is longer than a heel that is parallel to the dorsal hoof wall. Interestingly, it is the angle of the distal phalanx to the ground, and not the angle of the heel, that correlates well with the force on the navicular bone.⁹²

A long toe is associated with elongation and narrowing of the ground surface of the foot. The frog width decreases in a comparable manner with the width of the foot. The length of the frog should remain almost constant, so that an increase in the length of the ground surface of the foot is reflected in an increase in the distance between the apex of the frog and the most dorsal aspect of the toe or break-over point. The ground surface of the heel should be adjacent to the base of the frog. If the ground surface of the heel projects dorsally to the base of the frog, the heel is either too long, angled too acutely, or both. Hemorrhage in the white line at the toe caused by lamellar tearing may be a secondary indicator that the toe is too long.

In a horse with a broken-forward foot axis, a flexural deformity of the DIP joint must be distinguished from heel contraction secondary to pain. In a foot with a flexural deformity the heel and frog are more likely to be wide and the ground surface of the foot is triangular, resembling a hind foot. In contrast, a contracted foot has a narrow heel and frog.

The relationships between the individual phalanges and between the phalangeal axis and the hoof are determined radiologically. The phalanges are closest to alignment when the foot-pastern axis is straight. However, the proximal interphalangeal joint usually appears slightly extended (dorsiflexed), even with a straight foot-pastern axis.⁷⁴ The dorsal hoof wall should be parallel to the distal phalanx. The angle of the solar margin of the distal phalanx with the ground, the thickness of the sole at the dorsal distal margin of the distal phalanx, and the distance from the dorsal margin of the distal phalanx to the toe should be evaluated. The center of rotation of the DIP joint is assessed in relation to the weight-bearing surface of the toe and heel. Normally, the center of rotation should be slightly palmar to the center of the ground surface of the foot. Dorsopalmar imbalance is likely if the solar margin angle is less than 2 degrees, the center of rotation of the DIP joint is markedly shifted toward the heel, and the horizontal distance between the toe and dorsal margin of the distal phalanx is elongated.

In hind feet, dorsoplantar imbalance associated with hyperextension of the DIP joint appears to take a slightly different form compared with the fore feet. The dorsal hoof wall is not necessarily long when viewed from the side. The toe frequently has been dubbed back, and it acquires a marked convexity. Viewed from the ground surface the concavity of the sole is exaggerated, and if the foot is shod, the frog lies between the branches of the shoe. This may be from descent of the frog, or proximal displacement of the heel. In my experience, these horses almost invariably are shod.

Evaluation of dynamic dorsopalmar balance suffers from the same limitations as evaluation of dynamic mediolateral balance. However, gross imbalances can be observed with the horse at a walk or trot. Normally, when viewed from the side the foot is expected to land flat or slightly heel first.

TREATMENT OF IMBALANCE AND POOR CONFORMATION

Treatment of imbalance provides at least two challenges. The first is to have a clear objective of what ideal balance

is for any given horse because, although there are some hard and fast rules, other areas are unclear. For example, a straight foot-pastern axis is beneficial, but the exact length of toe that is optimal for the same foot is not clear.

The second challenge is interpreting the measured indicators of balance. For example, the measures of mediolateral imbalance, symmetry of the coronary band, sighting along the axis of the metacarpal region and across the ground surface of the foot, footfall, and dorsopalmar radiographs may not agree on whether the foot is imbalanced or the direction of the imbalance or may provide varying degrees of imbalance. Radiography appears to be the most accurate and is substantiated scientifically.⁹¹

Difficult balance problems may not have easy solutions, and judicious experimentation that can be both time-consuming and expensive may be necessary. Balance may be corrected, but long-standing problems may not be correctable. Poor conformation can be compensated for but can never be corrected with trimming or shoeing in an adult horse. The ability to compensate for poor conformation is inversely related to the height in the limb from which the defect originates. Major imbalances should be corrected gradually over time, or lameness may result from the correction.^{4,57,63}

Rebalancing the foot can be performed by visual assessment of the hoof and foot-pastern axis before and after trimming, repeating until a satisfactory result is obtained. Rebalancing may be facilitated by radiological assessment of balance. Radiographs, with markers to indicate the angle of the dorsal hoof wall, the location of the apex of the frog, and the position of the coronary band, obtained before trimming are used as a baseline on which to base the trim. Deformation of the hoof capsule in the pretreatment radiographs may result in underestimation of the imbalance,⁹⁰ and radiographs obtained after trimming may be helpful to assess the accuracy of treatment.

Treatment of imbalance is complicated by the necessity to consider both the immediate and delayed effects. The reversal of the immediate effects of imbalance is the most straightforward, because it requires nothing more than restoring the normal length of the wall around the circumference and ground surface of the foot. The effects of viscoelastic deformation of the hoof wall caused by uneven pressure should correct spontaneously if the force is removed and sufficient time is allowed before the horse is reshod. Other deformation of the hoof wall caused by contraction or aberrant hoof growth may have to wait for new hoof wall to grow from the coronary band to the ground surface after the biomechanical forces have been optimized by trimming and shoeing.

Horses with mediolateral and dorsopalmar imbalance may respond to trimming and allowing them to go barefoot.⁶⁶ Application of poultices to the foot has been advocated to encourage hoof realignment.⁸⁸ This allows the effects of prolonged imbalance from the viscoelasticity of the hoof and misdirected hoof growth to adjust without the influence of the shoe. However, the quality of a wall that is usually shod may deteriorate over several weeks before it improves, and flat-footed horses may become more lame.

In foals, trimming, shoeing, or surgery corrects poor conformation associated with abnormal angulation in either the sagittal or frontal (dorsal) planes. Conformation

in adult horses is fixed, but changing foot balance or shoeing sometimes can compensate for poor conformation. However, when the stresses are realigned to benefit a musculoskeletal structure, they become less than optimally aligned for the hoof capsule and predispose to a different problem. For example, in a horse with a long pastern at a normal angle or with a sloping pastern of normal length, the foot is further dorsal than is ideal. This creates a greater moment about the metacarpophalangeal joint. This can be compensated for in part by extending the heels of a shoe further past the heel of the foot than normal. This technique moves the most ground support palmarly, but it also moves the point of application of the GRF further palmarly, increasing both the stresses on the heel and the propensity to deform. Treatment of poor conformation is almost always a compromise.

Mediolateral Imbalance

Uncomplicated mediolateral imbalance is corrected by decreasing the length of the wall on the side of the foot in which it is longest, or lengthening the wall on the side that is shortest. If the horse has sufficient foot, it is always preferable to correct the imbalance by trimming the longer wall. However, when the hoof is insufficient to permit trimming the longer wall sufficiently to restore the equilibrium, then the shorter wall must be lengthened. A wall can be lengthened in several ways. However, care must be taken because alteration of the balance may actually cause lameness. The simplest method is to add a pad, either a shim or a full wedge pad. The shim pad is riveted to the branch of the shoe so that it is interposed between the foot and the shoe, or a full wedge pad is positioned so that the thickest portion of the pad is on the shortest side of the foot. Alternatively, the shorter wall can be lengthened by addition of acrylic. This can be allowed to set and a shoe nailed to the hoof and composite, or the shoe can be attached to the foot with the acrylic so that the position of the shoe in relation to the hoof capsule is adjusted as the acrylic dries.⁹³ A shoe with branches of different thickness can be used. This makes the thinner branch lighter. The width of the web can be increased to compensate for the thinner branch so that the asymmetrical effect of uneven weight distribution is minimized.

Flares and underrun walls that accompany mediolateral imbalance are frequently addressed at the time of shoeing through appropriate flare removal and shoe positioning. The longitudinal axis of the frog is a good guide to the location of the center of the ground surface of the foot in the sagittal plane. The shoe should be positioned symmetrically about the frog so that the flare that extends abaxially to the shoe is dressed back and the shoe extends abaxially past the underrun wall.¹ However, if there is distortion in the hoof wall, seen as displacement of the coronary band proximal to the flare, and there is exaggeration of the normal convexity of the wall where it is flared, then the flare is likely to return over one or more shoeing cycles. This distortion is most likely to resolve if the horse is allowed to go barefoot or, if feasible, the wall is floated at the point of the flare. If the hoof wall convexity and coronary band are not distorted, then the flare and underrun wall should correct as new hoof wall grows distally.

The most controversial issue in balancing a foot is restoring mediolateral imbalance in the following

circumstances: (1) when the coronary band is asymmetrical with one heel bulb or quarter higher, usually the medial quarter or heel bulb, which is obvious with the horse standing; (2) when the ground surface of the shorter wall appears farthest from the metacarpophalangeal joint when the axis of the limb is sighted with the foot off the ground; and (3) when the shorter wall contacts the ground first at a walk. This is typical with a sheared heel. Should the long wall be shortened, potentially increasing the discrepancy in foot-fall, or should the long wall be lengthened, exacerbating an already imbalanced appearance? I cannot see any benefit in lengthening an already long wall or determine how this might improve the wall. Radiological evidence of joint asymmetry may resolve the dichotomy. If this fails, the horse can be shod with a shoe positioned perpendicular to the axis of the limb with the long heel floated and extra support provided by a heart bar shoe.

Compensation for angular or rotational deformities in the limb of adult horses is seldom attempted because they are not the cause of pain, and attempts to compensate for them may increase the asymmetry of stresses imposed on the hoof capsule. However, if an angular limb deformity causes a secondary mediolateral imbalance, this may need correction whenever the horse is trimmed.⁶³ If a rotational deformity causes either the lateral or medial heel to land long before the other, aligning the shoe branches perpendicular to the axis of the metacarpal region rather than the pastern may be beneficial.⁵⁷ A medial or lateral extension may be used to extend the ground surface of the foot or shoe under the axis of the limb to improve the distribution of forces in the more proximal parts of the limb.^{3,57} However, these corrections improve function in one part of the limb at the expense of another. When angular or rotational deformities cause limb interference, it may be necessary to change shoeing to change the flight of the limb to reduce the likelihood of injury.

Dorsopalmar Imbalance

An imbalanced foot usually is related to a toe that is too long or a heel that is underrun, less frequently to a heel that is too long, and seldom to a heel or a toe that is too short. The toe or heel is trimmed until the horse has a straight foot-pastern axis. Because dorsopalmar imbalance starts to develop immediately after shoeing because of disparate growth of the toe and heel, deliberately trimming the foot 1 to 2 degrees broken forward may be useful.

Correction of a broken-back foot-pastern is more complicated after secondary changes have occurred. If excessive toe length has caused the sole to change shape so that it is longer and narrower than normal, the breakover should be brought back to a more natural position. The angle of the dorsal hoof wall should be reevaluated to determine whether it has improved before other measures are taken. In a barefooted horse the breakover is set by the trim, and in a shod horse by both the position and roll of the toe of the shoe. The foot width should increase naturally in time, and the shoe should be set full at the quarters to accommodate the abaxial movement of the quarters. An extended period may be required to regain the optimal ratio of the length to width of the ground surface of the foot. If an underrun heel is a result of a long-toe conformation, the weight-bearing surface of the heel can be moved palmarly (backed up), but the angle of the heel often is too acute to

allow alignment of the foot-pastern axis regardless of toe length. This can be corrected immediately by raising the heel. The heel can be raised with a wedge pad, either a full pad or shim, with a shoe with wedged heels, or by building up the heel with acrylic.^{3,94} However, this process increases the pressure on the coronary band at the heel and may decrease the rate of heel growth. Alternatively, a bar shoe may be used to limit the heel from digging into the ground.⁴ Allowing the horse to go barefoot may result in the fastest improvement in conformation, but this often precludes the horse working, and flat-footed horses may become more lame. Contraction of the width of foot often accompanies dorsopalmar imbalance, and grooving or thinning the heel has been recommended.^{1,65} For long-term soundness, I believe it is preferable to realign the foot-pastern axis as well as possible and then allow a wider, straighter heel to grow from the coronary band. This may require time out of work. Raising the heel is frequently the fastest way to return a horse to work; thus the manner of treatment may depend on the immediate athletic demands placed on the horse.

A broken-back hoof-pastern axis in the hind limbs is treated by trimming the toe, using radiography to assess the improvement. Frequently the solar margin of the distal phalanx is tilted by several degrees, with the dorsal margin farther from the ground than the plantar processes. In my experience, it may not be initially possible to improve the angle of the solar margin of the distal phalanx beyond parallel to the ground. It frequently is ideal to allow the hind feet to go bare. When the foot must be shod, in contrast to the fore foot, I recommend setting the toe of a rim shoe in line with where the wall at the toe should meet the ground and provide no more coverage of the heel than is necessary. It may be necessary to provide support to the ground surface of the plantar half of the foot.

Treating a broken-forward foot-pastern axis caused secondarily by pain or a flexural deformity by decreasing the dorsal hoof wall angle may exacerbate pain. A broken-forward axis resulting from pain must be addressed by treating the primary problem. Correction of a broken-forward foot-pastern axis associated with a flexural deformity is not always necessary, but when it is, it should be accompanied by desmotomy of the ALDDFT.

Compensation for a long pastern or a low foot-pastern axis when the weight-bearing surface of the foot is too far dorsal in relation to the limb may be achieved by extending the heels of the shoe.⁸⁸ This correction is directed at reducing the moment about the metacarpophalangeal joint by moving the palmar aspect of the foot or shoe farther palmarly, usually by using an egg bar shoe, but any heel extension that is not likely to result in the shoe being pulled by the hind foot will work. Compensation for an upright conformation is not readily feasible and fortunately is seldom necessary.

■ HORSESHOES AND SHOEING

Andrew H. Parks

An equine veterinarian must be able to assess the way a horse is shod in relation to the current use of the horse and make recommendations for shoeing to improve the function of the distal aspect of the limb. This necessitates

an understanding of the basic construction and fit of a shoe and its use. Determining how a shoe affects the horse's performance requires an understanding of how the elements of a shoe function. To understand how to change the function of the distal aspect of the limb, it is necessary to know which modifications to form and fit of a shoe can achieve the desired result. It is more important to consider how a basic shoe may be modified to achieve a given result than list a variety of different shoes for specific conditions. Farriery developed as an art guided by individual and collective experience and has recently been supplemented by scientific studies. Some guidelines are derived empirically and others have a scientific basis, but the skill of the individual is a vital third element.

HORSESHOES

Foot Preparation

Shoeing cannot be considered in isolation from foot trimming. The foot is trimmed to remove the excess length of wall that accrues because the distal aspect of the wall is protected from wear by the shoe. After the foot has been cleaned, the exfoliating sole and ragged margins of the frog are debrided with a hoof knife. The wall is trimmed with nippers and then leveled with a rasp.

In addition to maintaining optimal balance in a sound horse by trimming the foot to restore the length of the foot, several other modifications to the hoof capsule may be performed, usually with the intent of improving hoof capsule shape, and often in conjunction with specific shoeing practices. *Floating the hoof wall* refers to trimming part of the hoof wall short so that the hoof will not touch the shoe at that point. The shoe supports the wall on either side of the floated area dorsally and palmarly unless the heel is floated. Floating the hoof wall is used to relieve that section of the wall from weight bearing. This encourages faster growth at the coronary band, permits proximally displaced wall to descend, relieves stress in the wall so that new wall growth may redirect itself, and relieves pain. The heel is floated to treat an underrun heel. This is most effective when the palmar aspect of the foot is given additional support (e.g., with a heart bar shoe).

Grooving of the hoof capsule is designed to mechanically dissociate the capsule on one side of the groove from the other. The groove is made through the full thickness of the stratum medium. The grooves may be created parallel or perpendicular to the horn tubules. The use of several grooves parallel to the horn tubules between the quarters and heel of the hoof capsule has been advocated to encourage expansion of the heel by increasing the flexibility of the wall but is of dubious value. Grooves perpendicular to the horn tubules usually are made around part of the circumference of the hoof capsule immediately distal to the coronary groove, typically at the toe or heel. These grooves relieve the pressure on the coronary band from the stresses in the weight-bearing wall. This increases the speed of new wall growth proximal to the groove and allows the new wall to grow independent of distracting forces in the distal aspect of the wall.

Resection of the hoof capsule involves removal of the stratum medium, usually starting at the weight-bearing surface and extending a variable distance proximally, typically involving no more than 20% to 40% of the

circumference of the hoof capsule. Because this creates instability of the hoof capsule, it is used only for managing horses with laminitis, white line disease, and hoof wall avulsion injuries. Thinning the hoof wall at the heel so that partial thickness of the stratum medium is removed has been recommended to increase the flexibility of the wall and encourage expansion of the hoof capsule, but it is seldom performed.

The Horseshoe Form

In its most basic configuration a horseshoe is a curved steel bar, rectangular in cross-section, that is shaped to conform to the contour of the ground surface of the hoof wall and wide enough to cover the ground surface of the hoof wall and the immediately adjacent sole. The shoe has four surfaces: the foot and ground surfaces and the inner and outer edges, called *rims*. The parts of the shoe are named after the corresponding section of the hoof, that is, the *toe*, *quarter*, and *heel*. Each shoe has two branches, medial and lateral, that extend from the center of the toe to the medial and lateral heels, respectively. The substance of the branches is called the *web*, which has a width and thickness. The shoe is punched with nail holes, three or four in each branch, three of which are usually used. This shoe is described as *flat* because the ground surface of the shoe is level, *stamped (punched)* because it has nail holes, and *open* because the bar of metal forming the shoe does not form a continuous loop across the heel.

The shoe should fit flush with the outer margin of the dorsal half of the hoof wall from one quarter to the other. From the quarter palmarly or plantarly the shoe should incrementally extend further abaxial to the wall until it extends approximately 0.3 cm abaxial to the wall at the heel to allow for expansion and contraction of the hoof capsule as the foot alternates between weight bearing and non-weight bearing. The shoe branches extend marginally palmar or plantar to the heel to allow for growth of the hoof capsule during the shoeing cycle. This basic shoe pattern and fit may suffice for many horses but frequently is altered to suit the exercise performed by a horse or the ground surface on which the horse is worked and for therapeutic purposes.

Materials and Size

Horseshoes may be made of metal, synthetic polymers, or a composite of the two materials. Altering the material of a shoe alters the weight of a shoe for a given size, the durability of a shoe against wear and other damage, shock absorption, workability, and cost. Most horseshoes are made of steel for reasons of effectiveness, cost, wear, and workability. Aluminum also is used frequently because it is lighter and easier than steel to cold forge, but it wears faster than steel and is not as stiff. Shoes recently have been made from various synthetic polymers and composites of more than one material and are used in specialty situations, but shoe status is in constant flux as new products appear on the market and others disappear.

Metal shoes may be hand forged from bar stock or manufactured. Hand-forged shoes offer the advantage of being customized to the individual foot. However, manufactured shoes are used far more frequently than hand-forged shoes because they save time and a wide range of shoes is suitable for most feet. Bar stock is usually

rectangular in cross-section and is available in different sizes varying from 0.6 to 1.2 cm thick and 1.2 to 3.1 cm wide, although the most commonly used size is 0.8 × 1.9 cm. Concave stock is frequently used in Europe. Manufactured shoes, also called *keg shoes*, are sized. However, although sizing within and usually among product lines is consistent for a given manufacturer, there is no universal standard for sizing horseshoes. Manufactured shoes may be generically shaped to the general shape of a horse's foot or specifically designed for a fore or hind foot. The former require more shaping but are cheaper and require less stock on hand. The dimensions of the stock of either manufactured or hand-forged shoes affect the weight of the shoe, stiffness, coverage of the ground surface of the foot, height the shoe elevates the foot off the ground, and rate at which the shoe wears out.

Shoe weight influences biomechanics of movement. The heavier the shoe, the more energy is expended accelerating and decelerating the limb at the beginning and end of each stride. Therefore the lightest shoe is used that is compatible with protecting the wall and adjacent sole and providing the stiffness and wear required. Shoes made from concave stock are lighter than shoes made from regular bar stock. The width and thickness of the shoe usually are uniform around the circumference of the shoe so that biomechanical influence of shoe weight and the stresses imposed are usually balanced about the axis of the limb. Occasionally a shoe may be unevenly weighted to alter the animation or balance of a gait. The increased weight may be at the toe, in one branch, or at one or both heels. Increasing the weight at the heels is done to increase animation but has not been scientifically tested. Increasing the weight of the toe has been used to encourage the horse to reach farther at the beginning of the stride. Toe weights do not increase stride length but do increase flexion in the limb of horses with poor limb flexion during protraction of the limb. They have no impact on horses that already have good limb flexion.¹

Although the width of the web of a shoe is related to the thickness of the hoof and, at least in part, the size of the foot, it is common to increase the width of the web of the shoe to provide increased protection to the margins of the sole. The thickness of the shoe is related to the rate at which it is expected to wear and to a lesser extent the rigidity needed to prevent the shoe from bending out of shape. The height the shoe raises the foot off the ground also is influenced by the thickness of the shoe, but this is usually a secondary consideration to wear and rigidity.

Cross-Sectional Profile of Shoe Stock

The cross-sectional profile of the shoe may be modified by altering the ground surface, the solar surface, either rim of the shoe, or a combination and may affect the whole shoe or part of the shoe, such as the toe, the branch, or a heel (Figure 27-6).

Several common modifications are made to the ground surface of the whole shoe. Softening the 90-degree angles at the junction of the ground surface of the shoe and the inner and outer rims by beveling or rounding, called *rolling*, increases the ease of breakover. A shoe with a rounded outside rim is called a *roller motion shoe* and improves the ease of breakover in any direction. A similar effect is achieved with a *half round shoe*, so called because it is made

from half round stock that resembles a semicircle in cross-section. The toes of flat shoes frequently are rolled or beveled only at the toe to improve the ease of breakover (Figure 27-7). A similar effect is achieved by rockering the toe, that is, bending the full thickness of the shoe

proximally. Less commonly, a flat shoe may be asymmetrically beveled or rounded to improve the ease of breakover toward one side or other of the shoe to encourage a horse to breakover toward that side and direct the flight of the foot. Rounding the margin of a shoe to prevent interference is called *safing*.

There is little traction between smooth steel and the ground. Grooves in the ground surface of the shoe, called *fullering* or *creases*, increase traction. The fullering fills with dirt; the friction between dirt in the fullering and the dirt on the ground is greater than steel on dirt. In addition, the crease provides two additional edges that may bite into the ground. The full circumference of the shoe may be fullered, or it may be limited to the branches of the shoe and less frequently just the toe. Fullering a single branch of the shoe enhances traction uniaxially and delays breakover on that side of the foot. When the branches of the shoe are fullered, the nail holes are centered in the groove, which is formed to conform with the inside and outside of the nail heads.

Fullering and modifying the shoe edges frequently are performed in conjunction with each other. Rim shoes are fully fullered, and the ground surface of the rims is beveled toward the fullering of the shoe. More specialized rim shoes have a higher inside or outside rim, hence the names *inside* or *outside rim shoes* (Figure 27-8). A polo plate is a specialized form of inside rim shoe. Because the higher rim is on the inside, the horse is less likely to cause severe injury to another horse in competition yet still benefits from the additional traction of the rim. A barrel racing shoe is a form of outside rim shoe that provides greater traction than an inside rim shoe, although ease of breakover is sacrificed. A similarly modified profile of racing or training plates is termed *swedging*. A classic example of a shoe that

Fig. 27-6 • The cross-sectional profile of the shoe branch can be modified to vary traction and breakover. **A**, Half round. **B**, Flat shoe incompletely creased or fullered. **C**, Concave stock. **D**, Fully creased rim shoe. **E**, Incompletely creased rim shoe. (Eventer, St Croix Forge, Forest Lake, Minnesota, United States.)

Fig. 27-7 • The toe of a shoe frequently is modified to move the point of breakover palmarly compared with a flat shoe. **A**, Flat shoe. **B**, Rolled-toe shoe. **C**, Rocker toe shoe.

Fig. 27-8 • Cross-section of the branch of three shoes. **A**, A high inside rim. **B**, Rims of equal height; **C**, A high outside rim.

uses all these techniques is a half round, half-swedge shoe worn on the hind feet by harness horses. The inner branch is half round in cross-sectional profile, and the lateral branch of the shoe is swedged. Thus the medial branch, enhanced by the half round, breaks over rapidly, whereas the breakover of the lateral branch is delayed by the swedge.

The only common modification to the solar surface of the shoe is gentle beveling of the inner half of the web toward the inside, called *seating out* or *concaved inner surface*. Horses with flat soles are shod with seated-out or concaved shoes to decrease pressure on the sole adjacent to the wall. Less frequently the heels of the shoe are beveled to the outside margin of the shoe to encourage heel expansion, that is, abaxial movement of the wall during weight bearing. This practice is of questionable benefit, and if the shoe is beveled severely, it causes undue stress in the white line. Beveling the part of the heel of the shoe that extends abaxial to the quarters and heels, called *boxing*, decreases the likelihood of the shoe catching on another object or being trod on by another foot and pulled off.

Extensions

An *extension* is any projection of the shoe that extends outward from the normal outline of the shoe in the horizontal plane (i.e., away from the center of the sole). Extensions may be positioned anywhere around the circumference of the foot. An extension can be forged with the shoe at the time of manufacture or welded onto the outside rim of the shoe. A similar effect is obtained by using an oversized shoe positioned either forward or backward or by setting one branch of the shoe wide. Every extension has the potential to cause the shoe to act as a lever, and this lever action may be either static, when the horse is stationary and the foot bearing weight, or dynamic, particularly during the landing and breakover phases of the stride. When force is exerted on the extension by the ground, the stresses are increased in the adjacent wall and decreased in the opposite wall as the point of action of the GRF shifts. Because the digit is approximately symmetrical in the sagittal plane, the effect of medial or lateral extensions is similar. However, the absence of dorsopalmar symmetry means that dorsal and palmar or plantar extensions function differently. In addition to acting as levers, extensions increase the surface area available for ground contact, which decreases the amount the shoe descends into soft footing at that point in the circumference of the foot. If the surface area of one part of the shoe is altered, it causes

the foot to be supported by a soft ground surface more than the opposite side so the interaction between shoe and ground becomes more complex because the foot is tilted.

Abaxial extensions may be used to either force the opposite wall of the hoof capsule to the ground or support the wall adjacent to the extension. In doing so, the lever decreases the compression in the opposite wall and increases the compression in the ipsiaxial wall, which imposes a moment in the frontal plane. This effect is used in foals with angular deformities. The extension is placed on the opposite side of the limb to the side of the deviation to increase the load in the side of the limb with the extension, to slow growth, and to apply an angular force across the midsagittal plane of the limb.

Toe extensions usually are applied to foals with a flexural deformity of the DIP joint. The toe extension increases the moment about the DIP joint at breakover, as the point of action of the GRF moves dorsally, and during weight bearing if the heel is off the ground. This increases tension in the DDFT and muscle. Therefore the toe extension acts to stretch the musculotendinous unit of the deep digital flexor (DDF). Success depends on the severity of the flexural deformity. In more severely affected foals the pain generated by the increased tension in the DDFT, with or without increased compression at the toe, becomes counterproductive. The change in location of the GRF places the wall at the toe under greater compression, and it is prone to deform.

Heel extensions frequently are used uniaxially or biaxially. In performance horses, extensions frequently take the form of short continuations of the heel that are called *trailers*. Trailers are used almost exclusively on the lateral branch of hind shoes. Front shoes with trailers are likely to be removed by interference from a hind foot. Egg bar shoes project palmar or plantar to the heel of the hoof capsule and act as heel extensions. They are most commonly used on the front feet, where they are less likely to be removed by interference than shoes with trailers. Force on a biaxial heel extension decreases the moment about the DIP joint and the tension in the DDFT. Therefore horses convalescing from a DDFT injury benefit from heel extensions, frequently used in conjunction with heel elevation. Horses with navicular disease appear to benefit from egg bar shoes. The egg bar shoe acts as a palmar extension, and when the horse is on a soft surface it reduces the sinking of the heel into the surface at the beginning of the stride and acts as a heel wedge during the support phase of the stride.² Heel wedges are known to decrease the force on the navicular bone.³ The consequence of this benefit is that the heel is under greater compressive stress.

Heel extensions alter the way the foot strikes the ground. If, as happens frequently, the heel is closer to the ground at impact, the extension contacts the ground first. A lateral uniaxial extension, either in line with or diverging up to 45 degrees from the midsagittal plane of the foot, is used to force the foot to pivot toward the side of the trailer as the foot lands. The toe of the foot is directed laterally after impact and breakover is redirected.

Bars

A *bar* is any part of a shoe that extends from one branch of a shoe toward the other. A *complete bar* extends from one branch to the other; a *partial bar* extends part of the

way across the shoe. Most bars extend from one heel bulb to the other to form a closed shoe. A bar may extend from one quarter to the other, or even diagonally across the shoe. There are several patterns of complete bar shoes in common usage, including the straight bar, egg bar, heart bar, and heart bar–egg bar (or full-support shoe). Bar shoes offer several benefits: increased stability and ground contact surface area, local protection, and recruitment of additional weight-bearing area of the foot.

Closing the shoe is considered to make the shoe more stable by decreasing movement between the branches of the shoe and is frequently used, often in conjunction with other shoeing techniques, for instability within either the hoof capsule or distal phalanx. Bars that extend palmar or plantar to the normal position of the heel of the shoe act as a palmar or plantar extension. Bars that set under the ground surface of the foot can be adjusted to protect that part of the foot from ground contact, apply pressure to that part of the foot, or recruit that part of the foot for weight bearing. A straight bar shoe may decrease pressure on the palmar or plantar third of the frog and protect the underlying navicular bone. The heart bar shoe is used to recruit or increase the role of the frog in weight bearing, particularly in the treatment of horses with laminitis. However, heart bar shoes also may be used to support the palmar or plantar aspect of the foot to reduce the stress in the adjacent wall and permit floating of the heel.

An incomplete bar extends part of the way across the ground surface of the foot, most commonly from one heel bulb onto the frog, which supports or reduces weight bearing on a single heel bulb. Alternatively, a full bar across the full width of the foot may be used in conjunction with an incomplete shoe so that the bar covers both heel bulbs, but the shoe is incomplete between one quarter and heel bulb. The bar of a Z bar shoe is shaped with two 90-degree bends that are incorporated into a three-quarter shoe, so that one leg of the Z is attached to the heel bulb of one branch and the other is attached to the quarter of the opposite branch. This shoe also relieves one heel bulb from weight bearing.

Calks, Grabs, and Other Devices Added to the Ground Surface of the Shoe

Various devices are added to the ground surface of a shoe to increase traction. Shoe additives also influence the speed and direction of landing and breakover. Calks are projections of almost any size and shape, although most are round, square, or rectangular, on the ground surface of a shoe (Figure 27-9). The terminology to describe the different types is confusing and at times inconsistent. Different types are called *blocks*, *stickers*, and *studs*. They are made of steel or steel with a tungsten carbide core. Toe grabs and bars welded to the shoe are, in essence, greatly elongated calks. Borium, tungsten carbide crystals in a flux, is welded onto the surface of a shoe in an incremental manner so that any shape or sized projection can be formed. Some calks are permanent, whereas others are temporary. Permanent calks are forged with the shoe, molded in the case of aluminum shoes, at the time of manufacture, or welded or brazed onto the shoe at the time of fitting. Drive calks are semipermanent and are driven into a hole drilled into the shoe. Temporary calks, also called *screw-in calks* or *studs*, are screwed into tapped holes so they can be attached and

Fig. 27-9 • Calks may be forged with the shoe at the time of manufacture or added later. **A**, Calk of a “heeled” shoe formed at the time of manufacture. **B**, Calk formed by addition of borium. **C**, Various sizes of screw-in calks. **D**, A block inserted into an aluminum shoe at the time of manufacture. **E**, A sticker inserted into an aluminum shoe at the time of manufacture. **F**, Drive-in calks.

removed as needed. Cotton wool is used to plug the hole when not in use. The size and shape of the studs may be changed with the ground conditions.

Calks may be positioned at any point around the circumference of the shoe. The choice of whether to use calks, what type of calks to use, and where to position the calks follows no dogmatic guidelines but usually is based on the preference of the farrier. However, although square and round calks probably offer equal resistance to both medio-lateral and dorsopalmar motion, rectangular calks offer greater resistance to motion against movement perpendicular to the long axis. Bilateral heel calks typically are used on jumpers and event horses. Racehorse shoes may be equipped with toe grabs, with or without one or two heel calks (blocks or stickers). Draft horses usually have shoes with biaxial heel calks and, less frequently, a large toe calk.

Projections from the surface of the shoe, in addition to providing traction, inevitably alter the balance of the foot by altering the way the foot contacts the ground. The harder the ground surface, the greater the effect. The taller the calk, the greater the effect. A single calk at either the heel or toe alters mediolateral and dorsopalmar balance. Two heel calks of equal height alter dorsopalmar balance. The addition of a toe calk of equal height restores dorso-palmar balance. The addition of calks to the shoe concentrates stress in the wall immediately proximal to the calk. Therefore the lowest broadest calk compatible with adequate traction is recommended.

The effect of calks on breakover and landing is a secondary consideration, because other methods usually are applied to achieve the same objective. A single heel calk acts in much the same way as an extension, causing the foot to turn toward the side with the calk as the foot lands. Symmetrical placement of two pairs of calks, one pair on either side of the toe and one pair at the heels, encourages the foot to break over in the center of the toe.

Pads

A pad is a layer of material inserted between the hoof capsule and the shoe (Figure 27-10). Pads may provide protection, diminish concussion, and alter the effective angle, length, or both of the foot and shoe. Traditionally

Fig. 27-10 • Pads are inserted between the shoe and the foot and take various forms. **A**, Full leather pad. **B**, Full plastic pad. **C**, Oval plastic rim pad. **D**, Full wedge pad. **E**, A bar wedge pad. **F**, A full plastic pad formed with a molded heart bar. (Cushion Frog Pad, Castle Plastics, Leominster, Massachusetts, United States.)

they have been divided by form into full and rim pads, and by composition into leather and synthetic. However, in the last two decades an imaginative range of products has become available, a range too great for comprehensive discussion. Pads may be riveted to the shoe, which is then nailed to the foot. However, shoes are available that are manufactured with a rim pad bonded to the shoe. Full pads are fitted between the foot and the shoe and cover the entire ground surface of the foot. The cavity between a full pad and the sole usually is filled with pine tar and oakum, or a synthetic equivalent such as silicone, to prevent the cavity filling with dirt. In contrast to full pads, rim pads are fitted to the contour of the shoe so that the sole is not covered.

Pads that cover the sole protect the ground surface from direct trauma. However, efficacy has been questioned because the pad and packing effectively lower the contact point with the ground. Pressure on the pad can then be transmitted to the sole, although in a more diffuse pattern. Any pad interposed between the shoe and the wall has the potential to diminish concussion on the wall. However, products vary greatly.⁴ Wedge pads, either full pads or bar wedges, change the angulation of the hoof capsule to the ground. Wedge pads most commonly are used to raise the heel. Wedge pads also are used to raise either the medial or lateral wall to improve the mediolateral balance when this is not feasible by trimming. This can be achieved with a full pad, but it is more common to use a uniaxial wedged shim.

More novel pad designs include extension of the ground surface of the pad between the branches of the shoe to fill part or all of the cavity between the ground and the sole to form a flexible heart bar, or to recruit more weight-bearing surface area and support the ground surface of the foot. Similarly, silicone putty and pour-in polyurethane can be applied to form a pad in situ after the horse has been shod. Once set, these materials can be trimmed to selectively apply or relieve pressure.

Pads have several disadvantages. All pads compress, which causes the nails to loosen sooner than they otherwise would. Full pads trap moisture against the sole and frog. The underlying sole and frog are softer, and the horse is predisposed to developing thrush.

Miscellaneous Changes in Shoe Form or Fit

A shoe shape is not limited to covering the entire ground surface of the wall. Partial shoes cover part of the circumference of the hoof wall. Tips that cover just the toe are used to prevent wear at the toe in young horses. A three-quarter shoe extends from one heel to the opposite quarter and limits weight bearing in the uncovered heel bulb. A shoe may be reversed so that it is open at the toe but closed at the heel. This functions as an egg bar shoe palmarly with a shortened breakover at the toe.

Hot versus Cold Shoeing

In cold shoeing a previously manufactured shoe is shaped cold and applied to the trimmed foot. In hot shoeing a newly forged shoe or a manufactured shoe is heated in the forge and applied to the ground surface of the foot while the shoe is still hot. The heat sears and levels the trimmed surface of the foot. It should cause no discomfort to the horse. Cold shoeing is quicker and requires less equipment and less skill. Hot shoes are easier to shape than cold shoes because the steel is softer. Hot shoeing produces a better fit, because the searing levels any minor irregularities in the trim and highlights any overtly unlevelled areas. This is no substitute for correct trimming of the foot beforehand. The searing also aids seating of clips. It is also considered to seal the ends of the horn tubules.

Attachment of the Shoe to the Hoof

The large majority of horseshoes are attached to the hoof capsule with nails. Horseshoe nails are available in a variety of styles and sizes, but all share a similar pattern. Each has a head, a shank (blade), and a point beveled at the tip. There are several types of head that vary in size and the angle of bevel. Heads with less bevel, such as European head nails, are suited for thicker webbed shoes. Other nails with thinner or narrower shanks, such as race and slim blade nails, minimize damage to the wall. The size and style of nail are chosen based on experience to provide secure attachment of the shoe to the hoof capsule, without unnecessarily damaging the hoof capsule. The shape of the crease and nail hole should be stamped to fit the shape of the nail head, which provides the greatest support to the nail. The heel nail is located at the bend in the quarter, the toe nail at the junction of the toe and quarter, and the quarter nail(s) evenly spaced in between. In North America, three nails are usually used in each branch of the shoe. In the United Kingdom, three nails are usually used in the medial branch and four nails in the lateral branch.

The nail should be driven into the ground surface of the foot at the outside of the white line and exit the wall approximately 1.9 cm proximally. The bevel at the point of the nail is always directed toward the sole to limit the likelihood of the nail entering the underlying sensitive structures. Once the nail is driven, only the flat head of the nail should extend distal to the shoe. Because there is some variability in thickness of hoof wall for a given sized foot, the position of the nail hole in relation to the thickness of the web should be adjusted so that it is immediately distal to the white line. When the nail holes are positioned more toward the inner rim than normal, the shoe is coarse punched; when they are toward the outer rim, the shoe is fine punched. Because the slope and thickness of the wall change between the toe and

quarter, the angle at which the nail is driven decreases from toe to heel. This should be reflected in the stamping of the nail holes. These adjustments to the position, shape, and angle of nail holes are easier to accommodate on hand-forged shoes, although modern manufactured shoes are available in sufficient variety and made to such stringent specifications that most situations can be addressed satisfactorily. The number of nails, the size of the nails, the congruency of the nail holes to the shoe, and the skill with which the nails are applied determine the security of attachment of the shoe to the hoof. Small nails may not adequately attach the shoe to the foot. Large nails may split the hoof capsule.

Recently the use of various adhesives to attach shoes has become more popular. The shoe can be affixed with an adhesive by either tabs or cuffs that are attached to the circumference of the shoe and extend proximally. The cuffs are made of semirigid plastic or synthetic cloth. Alternatively, the adhesive may be directly interposed between an aluminum shoe and the ground surface of the wall and immediately adjacent to the sole. Attachment of the shoe with adhesives offers several advantages over nailing: (1) it can be used when nailing is too painful; (2) it can be used when there is insufficient wall for nailing the shoe; and (3) depending on the specific application, it permits greater expansion of the foot. However, there are disadvantages. The glue-on shoes or the adhesive are more expensive, and application of some adhesives to the side of the wall decreases the quality of the underlying wall over time. There is also a perception that glued-on shoes do not stay on as well as nailed-on shoes, but this impression is in part the result of poor case selection or poor application.

Clips are triangular-shaped projections that extend proximally from the periphery of the solar surface of the shoe. Clips may be forged from the shoe at the time of fitting, or shoes with preformed clips may be purchased. When a shoe is fitted, the outer surface of the clip is congruent with the surface of the hoof wall. Clips reduce movement between the shoe and the hoof capsule, which decreases the shear stress on the hoof nails. A single clip usually is used in the center of the toe of fore shoes, and two clips are placed near the toe quarter junction of hind shoes. A toe clip is not used on hind feet in case it should injure the fore foot, but there is no reason why side clips should not be used on fore feet. For additional stability of the hoof capsule, clips may be positioned elsewhere around the periphery of the shoe to constrain expansion of the hoof capsule. Optimally, two or more clips should be located at 180 degrees to one another around the circumference of the shoe so that the flat surfaces of the clips are aligned perpendicular to the direction of expansion.

Horseshoe Functions

The principal objective of shoeing a horse is to provide protection to the hoof wall from excessive wear. More far-reaching goals include improving balance, providing traction, modifying breakover, increasing animation, providing support or stabilization, and limiting interference.

Balance

Mediolateral and dorsopalmar balance are discussed elsewhere (see pages 288 to 293).

Protection

Shoes and accessories can provide protection from excessive wear, trauma, and excessive concussion. Protection from excessive wear is primarily required for the ground surface of the wall and is provided by any shoe that is interposed between the foot and the ground around the full circumference of the hoof wall and the adjacent sole. Protection of the rest of the ground surface of the foot, namely, the sole and the frog, may be achieved by interposing a layer between the ground and the ground surface of the foot. If a specific area needs protection, frequently this can be provided by modifying the shoe. For example, a seated-out wide-web shoe protects more of the sole adjacent to the wall than a shoe with a narrower web. A bar added to the shoe protects the underlying sole or frog. For more extensive protection to the ground surface of the foot or alleviation of concussion, a pad may be inserted between the shoe and the foot (see page 297). Some shoes are manufactured with a composite of a metal backbone to provide rigidity and synthetic polymers to provide protection against concussion.⁴

Traction

Traction is required to facilitate optimal, confident movement of a horse over the ground as the limb decelerates at the beginning of the stride, as the horse propels itself forward and around turns, and as the foot breaks over. There is an indirect inverse relationship between traction and ease of breakover. Many modifications to a shoe that increase traction delay breakover and vice versa. The amount of traction required depends on the horse, the type of exercise, and the ground surface. Decreased duration of deceleration at the beginning of the stance phase of the stride, as the foot slides before it becomes stationary, has been associated with an increase in the amplitude of horizontal shockwaves associated with initial ground contact.⁵ However, it appears that the horse adjusts its gait for different shoe materials so that the duration and distance associated with deceleration are similar, despite demonstrable differences in dynamic friction between different shoes types and the ground.⁶

Increased traction is provided by decreasing the ground surface area of the shoe, creasing or fulling the shoe, adding ridges to the cross-sectional profile of the shoe, or using calks, grabs, and nail heads that project below the surface of the shoe. Increasing the ground surface area of the shoe or rounding the outer rim or both rims of the shoe reduces traction.

Breakover Modification

The speed of breakover is related to the moment created about the DIP joint by the dorsal hoof wall at the end of the stride. This is determined by the anatomical relationship between the center of rotation of the DIP joint and the most dorsal point of ground contact, termed the *breakover point*, and the shoe's resistance to being elevated off the ground. The moment about the DIP joint is dictated by the direct distance between the center of rotation of the joint and the breakover point and the angle this line forms with the ground. These are in turn influenced by the length and angle of the dorsal hoof wall. Breakover can be enhanced by shortening the toe, moving the breakover point palmarly and increasing the angle of the dorsal hoof

wall. Breakover is delayed by lengthening the toe⁷ and decreasing the angle of the dorsal hoof wall.⁸ Shortening the toe is accomplished by trimming the foot and is limited by the underlying sensitive structures. Toe length can be increased by letting it grow out or addition of pads or a thicker webbed shoe. The breakover point can be moved palmarly by trimming a barefooted horse or rolling or rockering the toe of the shoe, squaring the toe of the shoe, or setting the shoe back. The use of rolled or rockered toes does not influence the timing of breakover.^{9,10} However, rolling the toe does smooth out the hoof-unrollment process and decreases peak load during breakover.¹¹ The angle of the dorsal hoof wall may be increased by elevating the heel with wedge pads or using shoes with wedged heels. These practices are both preferable to leaving the heel long. The degree to which the shoe adheres to the ground is directly related to modifications made to the shoe to enhance traction.

The direction and the point on the circumference of the hoof at which breakover occurs are related to the conformation of the limb, namely, the presence of angular or rotational deformities. To change the breakover point, either the orientation of the shoe on the ground before breakover or the ease of breakover between the two branches can be changed. The direction the foot is oriented on the ground is influenced by the way it lands, and the way it lands is influenced by the path of the foot during the flight phase of the stride, which is in turn influenced by the way the foot breaks over to complete the full phase cycle. Uniaxial trailers and heel extensions turn the foot ipsilaterally at landing, which directs breakover toward the opposite side of the toe at the end of the stride.

Breakover may be redirected by changing the relative ease with which the branches leave the ground, the relative length of the lever arm, adherence of the two branches of the shoe to the ground, or a combination of these factors. Adherence is increased by use of traction devices or decreased by using a nonfullered branch. The length of the lever arm of a shoe branch may be increased by setting it more dorsal to create a small extension between the center of the toe and the toe/quarter junction or decreased by setting it back. In essence, this is what happens when the toe is squared. Increasing the ease with which one branch lifts off the ground, while decreasing the ease as the other branch lifts off, shifts the breakover point toward the side with slower breakover. Any maneuver to change the direction of breakover is accompanied by increased torsional stress in the limb.

Animation

Gait animation indicates increased range of joint movement with exaggerated temporal characteristics. Animation is primarily a cosmetic change created because such characteristics are considered esthetically desirable in certain equestrian disciplines. It may be improved by shoeing.¹² Increased animation of gait is achieved by increasing the weight of the foot and shoe and increasing the length of the foot, shoe, or both.⁷ These manipulations delay breakover, which is then followed by an exaggerated response both in distance moved and joint angulation. Animation obtained by increasing the length of the foot creates imbalance and increases stresses associated with moments about the DIP joint. Animation obtained through increased

weight of the foot is accompanied by greater energy expenditure by the horse, fatigue, and a greater chance of injury. Interestingly, egg bar shoes decrease animation compared with flat shoes.³

Support

Support is a term widely used, seldom defined, and often ambiguous. Support usually means to hold a structure up or prevent it from collapsing. This can be interpreted in at least two ways. First, it can refer to the relationship between the foot and the ground. Second, it can refer to supporting a structure within the foot. On occasion, support may fit both of these circumstances. Specifically, supporting the foot in relation to the ground implies keeping the whole or part of the foot from descending into a ground surface that gives, or keeping the foot level. Increasing the ground surface area of the shoe at any juncture around the periphery of the foot will support that area. Typically, the palmar aspect of the foot is most likely to be supported by the use of a straight bar or an egg bar shoe.

Support as a concept applied to structures within the foot is not always straightforward. Collapse of the hoof wall under excessive compressive strain is a simple example. However, in horses with laminitis or rupture of the DDFT, the distal phalanx displaces from its normal position; the concepts behind providing support, though, are quite different. In a horse with a ruptured DDFT the relationship between the distal phalanx and the hoof capsule is intact, whereas in a horse with laminitis it is disrupted.

An injured tissue may require stress relief. The clinician should determine whether the tissue is stressed under tension (tendons, ligaments, lamellae) or compression (bone, hoof wall), at what point in the stride the stress is greatest, and whether the stress is associated with weight bearing, moments about the DIP joint, or a combination of these two factors. The stresses that are greatest during the weight-bearing phase of the stride are redirected by altering the balance of the limb by trimming the foot, applying wedges, using shoe extensions as levers, or recruiting additional parts of the ground surface of the foot to bear weight. For example, in a horse with laminitis with uniaxial damage to the lamellae, the distal phalanx displaces distally on one side of the foot only, and the DIP joint becomes correspondingly asymmetrical. Support of the DIP joint requires an extension to the side of the displacement, but this would further increase the strain in the damaged lamellae and cause further displacement. To protect the lamellae, contralateral extension, used with other measures to support a laminitic foot, would load the contraaxial lamellae and protect the damaged lamellae by reducing the load. An ipsilateral extension would be appropriate to treat a strain of a collateral ligament of the interphalangeal joints. However, redistributing the stress from one structure inevitably increases the stress on others.

Decreasing the moment about the joint reduces stresses that are greatest during extension of the DIP joint. For example, in a horse with acute laminitis, the already damaged lamellae have a greater propensity to separate with the stress associated with breakover. To reduce this stress, shortening the toe decreases the length of the lever arm, and elevating the heel decreases the tension in the DDFT.

A strain of the insertion of the DDFT is under stress during both weight bearing and breakover. A heel extension with elevation decreases the stress during weight bearing by moving the point of action of the GRF palmarly. Moving the breakover point palmarly decreases the tension in the DDFT at breakover by decreasing the torque about the DIP joint. If the DDFT were severely strained, a heel elevation and extension would prevent the toe of the foot from lifting off the ground and subluxation of the DIP joint.

It is important that the practitioner understands which tissue to support, how to achieve this support, and what side effects must be anticipated. In addition to the immediate benefits of the support provided, the clinician must contend with the changes within the hoof capsule and changes in the relationship between the hoof capsule and the distal phalanx from movement between the epidermal and dermal lamellae, the viscoelasticity of the hoof capsule, and the altered pattern of growth of the hoof.

Prevention of Interference Injury

Interference occurs when the foot of one limb contacts another limb during the stride cycle, which frequently results in injury (see Figure 7-2). Interference can be divided into two types. *Brushing* occurs when a forelimb or hindlimb interferes with the contralateral limb between the coronary band and the carpus or hock. When a limb interferes with the ipsilateral limb, the hindlimb strikes the forelimb (forging, overreaching) or, less frequently, the forelimb strikes the hindlimb (scalping, speedy cutting). *Cross-firing* occurs when a forelimb and contralateral hindlimb interfere. The causes of interference include poor balance, poor conformation, fatigue, and lameness. When poor balance, or lameness, is identified as the cause, correction of these problems should resolve the interference. Increasing the fitness of the horse or using a lighter shoe may reduce interference from fatigue in unfit horses. However, the conformation of a horse cannot be changed. For example, a horse that is toed out will wing in during the flight phase of the stride, increasing the likelihood of interference with a contralateral limb. A horse with a short back in relation to the length of its limbs has an increased tendency for interference between a forelimb and a hindlimb. Treatment of interference that cannot be eliminated by removing the cause is directed at preventing interference by influencing the flight pattern of the feet and reducing the severity of injury when interference does occur.

Contact between ipsilateral limbs occurs as the forelimb is breaking over and the hindlimb is landing. Traditionally, prevention has been aimed at encouraging the forelimb to break over faster so that it moves out of the way of the hindlimb and delaying breakover of the hindlimb so that it lands later. Forelimb breakover has been discussed previously. Delaying breakover in the hindlimbs has been accomplished by lowering the heel of the hoof or thinning the branches of the shoe at the heel. However, although this does delay breakover, limb coordination is restored during the swing phase of the stride.¹³ It also creates a dorsoplantar imbalance, which may cause other problems.

Contact between contralateral forelimbs occurs because the path of the limb in the swing phase is too close to the position of the weight-bearing limb, which is most likely to occur in base-narrow, toed-out horses. Prevention aims

to redirect breakover laterally away from the medial aspect of the toe so that the phalanges do not diverge as far medially from the midsagittal plane of the limb as the metacarpophalangeal joint flexes.

Contact between a hind foot and the contralateral forelimb in pacers occurs between strides as the horse is suspended. Prevention of cross-firing is aimed at encouraging the hindlimb to stay further lateral so that it does not contact the forelimb. This is accomplished by encouraging the foot to move laterally as it lands, adding a trailer to the lateral branch of the shoe, and encouraging the foot to break over toward the outside of the foot by using a half round-half swedge shoe.

To decrease the severity of injury when impact between the limbs is unavoidable, the clinician should reduce the likelihood of the shoe itself, particularly sharp edges, from contact of the limb likely to be injured and directly protect the injured limb. To limit injury caused by sharp edges at the periphery of the shoe, the margin of the shoe can be safed in the area of contact, or a shoe with a curved contour, such as a half round shoe, can be used. To limit contact between the shoe and the injured limb, the shoe can be fitted so that it is set back from the margin of the hoof wall by moving the toe of the shoe back, reversing the shoe, or moving the medial branch axially. Alternatively, the shoe is forged so that the part of the shoe making contact is set back from the wall. Boots can be worn during exercise to directly protect the part of the limb likely to be injured.

THE PRACTICE OF SHOEING

Effects of Shoeing on Foot Function

A horseshoe is not simply an extension of the hoof capsule. By interposing a shoe that has markedly different physical characteristics from the hoof capsule between the foot and the ground, a single interface is replaced by two interfaces—that between the foot and the shoe, and that between the shoe and the ground. This inevitably has consequences for foot function.

A flat shoe nailed onto the hoof decreases movement of the hoof during the impact phase of the stride,¹⁴ although the heel is still able to expand.¹⁵ It increases the maximum deceleration of the foot,⁴ increases the frequency of vibrations within the foot as it strikes the ground,¹⁶ and maximizes vertical GRF.¹⁷ This influence of shoeing on the shock caused by foot impact decreases proximally to the point where the influence is minimal at the metacarpophalangeal joint.¹⁷ Shoeing does not change the principal compressive forces within the hoof wall, although it does cause slight reorientation and decreases the variability of the stresses within the wall.¹⁸ In addition, shoeing increases the pressure on the navicular bone by the DDFT³ and accentuates the decrease in tissue pressure within the digital cushion that occurs soon after impact.¹⁶ Shoeing increases stride duration, but not stride length, in young horses shod for the first time.¹² Shoeing and the addition of weight to a shod foot increase the animation of the gait.^{7,12} Shoeing has minimal effect on the point of force during the stride.¹⁹ It has been suggested that the rigidity of the shoe alters the way the hoof capsule accommodates to irregularities on the ground surface.²⁰ A rigid shoe causes the whole foot to tilt or twist, whereas the viscoelastic hoof capsule might permit local distortion of the hoof capsule with less displacement

of the whole foot. Finally, shod horses do not wear the feet naturally. Although virtually no wear of the distal hoof wall occurs between the toe and the middle of the quarter, because there is no movement of the hoof wall against the shoe, the heel does wear against the shoe as it expands and contracts.²⁰ Therefore during the course of a shoeing cycle, the angle of the dorsal hoof wall decreases.²¹

It is my impression that shoeing over a prolonged period results in a thinner hoof wall. The quality of the wall adjacent to the shoe is not as good as that of the same horse barefoot. It is also my impression that the distal phalanx may change shape as the result of certain shoeing practices and imbalance. Mediolateral imbalance may change the shape of the distal phalanx.²² Of greater importance is the effect of shoeing on the development of the feet of young horses. The feet finish growing when a horse is 4 to 6 years of age. If abaxial movement of the hoof is restricted by shoes before that age, it may affect the growth of the hoof and potentially the shape and size of the distal phalanx. I prefer to allow young horses to go barefoot until they are mature if the intended use of the horse permits.

The deleterious effects of shoeing have led to a resurgence of interest in maintaining horses barefoot with routine trimming as necessary. Although there are unquestionable benefits to keeping a horse barefoot, maintaining a horse under modern management conditions so that its feet are in a condition to withstand the demands of work without becoming lame can be challenging.

Shoeing Sound Horses for Performance

Routine shoeing is directed at maintaining optimal balance and foot function and then addressing any specific needs that are related to the nature of work the horse performs. Balance is discussed elsewhere (see pages 284 to 285). The specific needs of a horse for a given type of work often have an established tradition. Observation of how other horses competing in the same discipline are trimmed and shod is a good starting point. Farriers who specialize in shoeing horses competing at high levels are a valuable resource. Fads are as much a part of the present history of shoeing as they are of many other disciplines and should be viewed with circumspection. However, although most fads disappear, a few become part of the standard armamentarium. In addition to traditional guidelines, there are rules regulating certain trimming and shoeing practices set by the governing bodies of different branches of equine sports and competitions. These frequently regulate the type of traction devices, weight of shoe, or length of toe that may be used. These rules generally are aimed at limiting excessive injury to the horses. For example, the use of toe grabs is prohibited in racehorses in certain states in the United States because of the established association between use and severe musculoskeletal injuries. Polo ponies are allowed to compete with inside rim shoes on the fore feet but not outside rim shoes.

Corrective Shoeing

Modification of a shoe in the pursuit of one objective almost inevitably has other consequences, which may be untoward. For example, to alter the mediolateral imbalance of a foot by decreasing the thickness of the web of one branch, either the width of the web can be maintained

with loss of weight or the weight of the web can be maintained but the width must be increased. Changing the weight of the web alters the inertia about the distal aspect of the limb. Changing the width of the web potentially changes the traction between the ground and the shoe and the depth the shoe sinks into the ground surface.

Corrective shoeing is directed at preventing lameness in a horse with poor conformation or balance (see pages 285 to 293) or treating a horse that has become lame. Therapeutic shoeing of lame horses requires knowledge of the cause of the problem and how to treat it. Lameness usually is related to pain that is often the response to inflammation after low-grade repetitive injury or to insult from stresses within tissues or at the interface between tissues. These stresses may be compressive, tensile, bending, torsional, shearing, or a combination of these. For example, compressive strains within the sole result in bruising and, in some horses, osteitis of the distal phalanx. Bending or shearing stresses in the wall may result in hoof cracks. Long-toe, low-heel conformation increases tension in the DDFT, compression of the navicular bone, and tension within the dorsal lamellae.

Accuracy of the diagnosis may be the first impediment. Sometimes pain causing lameness can be isolated to a specific tissue with a combination of physical examination, local analgesia, radiography, scintigraphy, and magnetic resonance imaging, but frequently the pain can be isolated to only part of the foot, and sometimes simply to the foot. The precipitating factor may not be within the tissue or structure exhibiting pain but may be a conformational change elsewhere. The more accurate the diagnosis, the more closely localized the source of pain, and the more knowledge of any underlying stresses, the more appropriate treatment is likely to be and the greater the chance of success.

The less specific the diagnosis, the more symptomatic the therapy. This is most likely to be directed at the balance of the foot and conformation of the limb, not necessarily an easy task. However, if lameness and pain persist after optimal balance is restored, the pain is most likely to be related, directly or indirectly, to the concussive forces associated with impact and weight bearing or flexion and extension of the distal aspect of the limb. The ground surface of the foot can be protected from direct impact with the ground, and the maximal deceleration and frequency of vibrations within the structures between the ground surface of the foot and the metacarpophalangeal joint can be decreased. Extension of the DIP joint can be decreased by reducing the extent that the heel sinks into a soft ground surface and the moment about the DIP joint at breakover. Torsional stresses within the distal aspect of the limb may be reduced by encouraging the foot to break over in the most natural position.

Lameness Associated with Shoeing

Although the incidence of lameness associated with shoeing is unknown, poor trimming, shoe selection, and shoe attachment are well-recognized causes of lameness. Trimming that leaves a hoof too long or imbalanced, either mediolaterally or dorsopalmarly, predisposes the distal aspect of the limb to abnormal stresses and lameness. Similarly, trimming the wall and adjacent sole too short causes undue pressure on the sole, bruising, and lameness.

Shoe selection includes size, weight, and traction devices. If the shoe is too small or short for the foot, the heel is unlikely to have adequate coverage. Pressure is concentrated in the wall and adjacent sole, which leads to bruising, hoof cracks, and an underrun heel. Shoes that are too long or wide are at greater risk of being pulled off. If the ends of long branches are redirected axially to prevent the shoe from being pulled off, the angle of the sole may bruise. If the web of the shoe is narrow, the adjacent sole is unprotected. Conversely, a wide-web shoe may impinge on a dropped sole.²³ Shoe size influences its weight. A heavy shoe may cause fatigue, decreased agility, and predispose to interference.²³ The size of a shoe also affects the effective surface of the foot. Too small a ground surface area concentrates the stresses of weight bearing.

Inappropriate use of traction devices predisposes to injury. The use of calks and toe grabs alters the balance of the limb and concentrates stress wherever they are applied. Too much traction may cause shearing within the limb as the horse places the limb on the ground because the limb decelerates too rapidly. Traction devices that anchor the limb in the ground once the foot is planted may cause fractures of the McIII or the proximal and middle phalanges as a horse pivots on the limb. An inside rim shoe provides a good compromise among traction, ability to pivot, and ease of breakover. Too little traction at least decreases a horse's confidence as it works and at worst may cause a horse to slip and injure itself.

If a shoe is unintentionally set eccentrically, so that one branch extends further abaxially than the other, greater stresses occur in the wall proximal to that branch. If the shoe is unintentionally rotated, the coverage of the heel is uneven and the heel bulb with the least coverage responds as if the foot were shod short on that branch. If the shoe is to be rotated intentionally, a larger shoe should be used.

Inappropriate attachment of the shoe to the foot may cause direct injury to the underlying sensitive tissues, damage the hoof capsule, and impair expansion. The use of larger nails than needed displaces more tissue as they are driven and therefore is more likely to fracture the hoof wall or impinge on the underlying sensitive structures. Nails that directly injure the sensitive tissues when driven, called *nail prick*, cause an instantly recognizable problem that is immediately corrected. More insidiously, a nail that is close to but not within the sensitive structures, a condition called *nail bind*, applies pressure to the lamellae or may cause the inner hoof wall to fracture toward the lamellae. This creates a tract through which infection may become established. Nail prick and nail bind may occur because the nail was driven too high or was started too far axially. The angle at which the nail holes are punched and the location of nail holes in the web of the shoe may contribute to the problem. Nails set behind the middle of the quarter adversely affect the expansion of the foot and should be avoided.

■ NATURAL BALANCE TRIMMING AND SHOEING

Gene Ovnicsek

The feet of wild and domestic horses have the same anatomy, function similarly, and require stimulation to

develop and perform optimally. The equine foot is a product of its environment, and the foot modifies and changes so that the basic requirements for health, function, and soundness can be met. This works well when the horse is roaming free in an area that is large enough for optimal foot maintenance or, if used aggressively, barefooted. The sole, bars, and frog become callused and durable, with the wall chipping and wearing so that the wall at the toe is worn to the same level as the sole. Feet managed in this self-maintaining manner are of the highest quality and generally are trouble free and healthy.

APPEARANCE OF A SELF-MAINTAINED FOOT

The wall of a self-maintained foot is worn down to the level of the sole callus in the toe region. The quarters are broken away at the widest part of the foot in horses that live in soft and sandy areas. This allows dirt to compact only in the palmar region of the foot, in the area of the bars. The heel grows beyond the height of the frog, which helps to form a trap for the dirt. The wall is worn to the level of the sole dorsal to the frog apex. The frog apex is generally in contact with the ground when the foot is loaded and is often enlarged and callused as a result of its use. Radiology shows that this area is in the center of the distal phalanx. Support for the distal phalanx is provided by the dorsal wall and sole callus, frog apex and frog buttress, bars, heel, and dirt compaction.

Horses that are ridden or live in areas with more abrasive surfaces, such as pavement or dry gravel, frequently wear the heel shorter than the level of the frog. The wall is always worn equal in height to the sole in the front part of the foot (Figure 27-11). The thickness of the live sole callus (recognized as the functional epidermal sole tissue that extends beyond the dorsal distal border of the distal phalanx) at the toe, and the thickness of the live sole at the heel are a consistent distance from the distal border of

Fig. 27-11 • This imprinted feral foot shows the wall is worn to the same level as the sole at the toe. This is typical of self-maintained feet of both feral and domestic horses.

the distal phalanx.¹ Therefore the sole is a reliable reference for mediolateral balance. The wall can be trimmed or rasped to the same distance from the live sole on each side of the foot so that the distal aspect of the distal phalanx is level, parallel with the sole.

The quality of the frog and digital cushion plays a major role in dorsopalmar balance of the foot. The natural, healthy frog is designed to hold dirt between the bars and frog, and dirt seldom exceeds the level of the frog. The frog, along with the dirt compaction, is partially responsible for the alignment of the distal phalanx and the pastern. The frog, bars, and sole are all important in weight bearing.

The hoof wall breaks away while the sole and frog become callused and durable for the horse to walk on. With shod feet there is little control of the natural hoof wall trimming that occurs by wear and chipping. If the wall of a shod hoof is not prepared to a depth equal to that of the live sole plane medially and laterally, the coronary band distorts and quarter cracks and toe cracks may develop. Horses that break and crush the heel and those that develop toe cracks and quarter cracks all experience a natural but crude, deliberate way of trimming the foot so that the distal phalanx maintains a parallel medial to lateral orientation to the ground. Breaking and cracking of the wall allow the frog, bars, and sole to contact the ground to fulfill the natural function.

To maintain a horse barefooted without availability of a large, free-roaming area, owners should try to keep the horse's living area and exercising area the same. If a horse is kept in a soft, sandy pasture or large, sandy paddock, then it should be ridden daily in that same type of sandy terrain. The same is true for horses kept in dry, rocky pastures. In addition to a consistent environment, regular activity also is required, with exercise for 5 to 25 miles daily.

Most horses are housed in small, confined stalls or paddocks that are often soft, wet, and nonabrasive. The feet do not wear at all and adapt to that environment. These horses are reluctant to work barefoot on a more abrasive surface. Some horses have poor-quality, substandard feet that need some type of protection for any form of work.

NATURAL BALANCE TRIMMING FOR A BAREFOOTED HORSE

Natural balance trimming is maintaining the feet of domestic horses consistent with self-maintained feet. These instructions are for *domestic horses that are left barefoot*.

The majority of horses' feet can be separated into four types: (1) normal feet, (2) feet with an underrun heel and long toe, (3) clubbed or upright feet, and (4) unusually flat feet. In all types the sole callus, the apex of the frog, and the callused portion of the frog buttress are the support structures of the foot (Figure 27-12).

Normal Feet

The following trimming sequence is used for horses that have normal feet and are left barefooted without suitable activity to wear the feet to the natural hoof shape. After removal of dirt, the clinician should identify the sole callus in the toe area. This is the functional epidermal tissue that extends beyond the dorsal, distal border of the distal phalanx and is seen as the raised area just inside the hoof

Fig. 27-12 • Important support structures of the equine digit. **A**, Sole callus. **B**, Apex of the frog. **C**, Callused portion of the frog buttress.

wall. The sole callus maintains its relationship with the distal phalanx at the 10-o'clock and 2-o'clock positions, also commonly termed the *pillars*.² A line across the leading (dorsal) edge of the pillars is approximately 2.5 cm (1 inch) dorsal to the true, well-identified frog apex on medium-sized feet (feet from a large size #0 to a small #2). The *live sole* is the functional epidermal sole tissue that extends beyond the distal border of the distal phalanx and has a waxy surface appearance. The clinician should remove only enough of the loose, flaky, chalky sole material so that the live sole and the sole callus are clearly seen. Most horses left barefooted have little or no sole that needs to be exfoliated or removed.

The point of breakover occurs in the self-maintained foot at a line drawn across the toe at the back edge of the sole callus (leading edge of the pillars), or approximately 2.5 cm (1 inch) dorsal to the well-identified frog apex. With a normal foot the wall in this region is firmly attached to the sole callus at ground level. The sole callus on most normal bare feet is narrow and well defined, but not in flat or clubbed feet, because in these horses the toe of the distal phalanx is closer to the ground. The hoof wall should be conservatively rasped or nipped to the back edge of the sole callus. The rocker or roll should not exceed 10 to 15 degrees from the flat plane of the sole (i.e., what is normally found on a well-worn shoe). Next, the wall is trimmed and left slightly taller than the sole callus on each side of the toe, behind the rockered portion. The finished height of the wall should be approximately 1 to 2 mm closer to the ground than the sole callus. The length of that flattened, raised area of the wall depends on the size and type of the foot and sole callus (approximately 2.0 to 2.5 cm).

The wall behind the toe callus is trimmed to the level of the live sole through the quarters. The heel that remains is flattened so that the medial and lateral aspects of the heel are equal in height to each other and at the same level as the frog buttress or slightly shorter. This generally means that the quarters at the widest part of the foot are floated.

Only the cleft of the central sulcus of the frog is routinely trimmed to lessen the chance of bacterial colonization in less active horses. The rest of the frog should not be trimmed at all, unless parts are hanging by a small

attachment from the live frog structure. The bars are trimmed only if they start to turn, roll over, and become flat to the sole, or if cracked or diseased. If flares exist on the outer hoof wall, the clinician should find the most prominent growth ring near the middle of the dorsal hoof wall and remove only the amount necessary to make the wall straight from top to bottom. Rasping should not exceed half the original wall thickness, and the wall should have a fairly uniform thickness all the way around when finished. Finally, the outer rim of the hoof wall that is closest to the ground is rounded (the rim is chamfered).

Flat Feet

Horses with flat, sensitive feet that are used for trail riding and multiterrain activities often are unsuitable to leave barefoot. Many horses with flat feet have a thin sole that separates from the wall at ground level, causing laminar tearing at the distal aspect of the distal phalanx. With the sole callus used for weight bearing, the outer wall is removed in a dubbed, vertical manner to lessen the pull on the wall. The wall is brought back very close to the edge of the sole on the ground side so that no dirt will pack under the wall next to the sole. The sole of the foot is never touched with the knife or rasp. Feet of this type never need exfoliating. They need more sole thickness below the distal phalanx, which may develop if the wall is reattached closer to the ground surface of the sole. When the distal 3 to 4 cm of the wall is left to full thickness, the distal phalanx is supported proximally by stable wall. The sole callus may become more durable and develop dense protective tissue once the laminae are not torn by the wall pulling away from the sole.

The heel is rasped back to a solid horn structure, and the frog is left untouched. The clinician should not rocker the toe until the wall attaches more normally to the sole at ground level. With repeated trimming the gap between the sole and wall disappears, and eventually the callus at the toe quarters bonds tightly with the wall, and the solar surface may become concave.

Clubfeet

An upright or clubfoot often is smaller. The practitioner should not try to change it but should treat it separately, using the same guidelines as for a normal foot. The sole callus at the toe is located to determine the point for break-over. The live sole in the heel region is used as a guide for trimming the heel, leaving the sole full thickness to protect the distal border of the distal phalanx. In my opinion, the most fragile part of the horse's foot is the distal border of the distal phalanx; in an upright foot, it may be more susceptible to trauma. However, if the heel is lowered excessively while the toe is left to improve the digital alignment, damage to the distal border of the distal phalanx is more likely.

A normal foot has an even curve to the outer hoof wall at the heel buttress and an even arch to the bars, with the heel buttress terminating slightly ahead of the back of the frog. The heel buttress (end of heel) of an upright foot has an abrupt curve with bars that are quite straight. The heel ends close to the back of the frog. Excessive removal of the heel of a clubfoot does not allow the horse to land heel first and increases the chances of distal phalanx trauma from landing toe first.

The sole callus on a clubfoot is slightly different from that of normal feet. There is usually a broad, raised formation to the sole, seen just ahead of the frog apex. The callus on each side of the frog apex is more prominent and extends well behind the tip of the frog. The natural place for breakover is closer to the frog apex because of the position of the sole callus. Therefore the wall is rockered ahead of the sole callus just as in a normal foot. The live sole in the back part of the foot is deeper. The hoof wall at the heel should not be trimmed equal to the live sole. The sole callus continues palmarly to the widest part of the foot and beyond, giving the appearance of a flat, thick sole from the medial to lateral aspects of the heel. If the dorsal hoof wall is severely flared and resembles a foot with chronic laminitis, the flare should be removed.

Feet with Long Toes and Underrun Heels

An underrun heel grows forward under the foot with a sharp curve in the heel. The underrun heel ends ahead of the frog buttress with bars that are curved similarly. The frog apex is often elongated. This heel conformation is abnormal and often is painful. Natural balance trimming helps to restore the foot to a near natural shape, with alleviation of pain. The sole callus is broad and looks more like a small mound around the sole ahead of the frog apex. If the horse can be kept in a dry, soft area for 1 to 2 weeks, the toe can be aggressively rockered ahead of the callus, leaving the sole callus and medial and lateral walls to walk on. The heel needs to be trimmed back below the level of the frog if the bars and heel are severely curled and appear to end in front of the back of the frog. However, the heel should never be trimmed down past the live sole at the heel or any other part of the foot. The wall is finished normally. This aggressive trimming rapidly starts to repair the deformed feet and can be done quickly and successfully as long as the bottom of the foot is hardened and protected with hoof and sole hardeners. Alternatively, more wall can be left at the medial and lateral sole callus to not overload the sole callus. The foot will respond well with each trimming.

NATURAL BALANCE SHOEING

When preparing the sole surface for a shoe, the frog, bars, and sole are prepared conservatively, similar to feet that are left bare. Feet that are shod do not exfoliate effectively, and sole material that is showing cracks in the sole and is chalky and crumbles when it is cut with a knife should be removed. When the sole and frog material changes from a chalky, crumbly state to a waxy-appearing surface, the live or functional sole and frog has been reached, and absolutely no more cutting should be done. The live, functional sole at the toe quarters (where the sole callus is) and the live sole at the heel quarters (behind the widest part of the foot) are references to the distal border of the distal phalanx. Trimming the wall to these live, functional structures offers the best guide to attain accurate mediolateral and dorso-palmar balance.

The bottom surface of the foot is finished flat when the foot is prepared for shoeing (not relieved in the quarters as when trimmed to be left barefoot) and is hot seated if possible. Vigorous hot seating helps to dehydrate and strengthen the sole callus. It also pulls the sole proximally from the ground level to eliminate sole pressure.

Fig. 27-13 • The aluminum Natural Balance shoe is designed to be applied 0.3 to 0.9 cm (depending on foot size) from the frog apex to the inside edge of the shoe at the toe. This placement closely meets breakover requirements with respect to the sole callus. The seated-out reverse arch on the inside border of the shoe at the toe helps to protect the distal border of the distal phalanx from sole pressure.

Shoe Placement and Application

Shoe selection is important, and wide-web rim type shoes work best for easy modification. The outer rim is normally tapered-in to the nail groove, which is helpful and somewhat mimics the way the bare foot naturally wears. That same feature is equally helpful at the toe when the shoe is squared somewhat and positioned on the foot so the break-over point of the shoe fits directly over the back edge of the sole callus at the center of the toe. The heel of the shoe should extend to the full length of the frog. A good reference for that position is the back of the crease in the central sulcus. Radiographs can be used to determine the natural position for breakover.

When premade aluminum (Thoro'Bred Racing Plate Company, Anaheim, California, United States) or steel (Malaysian Horseshoe Company, Malaysia) Natural Balance shoes are used, the same criteria of shoe placement for breakover and heel length should be followed. A wide-web rim shoe is broadened at the toe and tapered from the inner rim to the toe between the toe quarters. The shoe is placed on the foot so that the inner rim (part of breakover) is over the inside edge of the sole callus. The Natural Balance shoe is positioned a variable distance from the frog apex to the inside edge of the shoe for placement (Figure 27-13). That distance is regulated with the heel position. If a line is drawn across the widest part of the foot where the bars end, one third of the foot mass is ahead of this line to the point of breakover.

■ HOOF RECONSTRUCTION MATERIALS AND GLUE-ON SHOES

Robert Sigafos and Patrick T. Reilly

Advancements in adhesive technology have substantially improved the dependability of adhesive-bonded shoes. The incorporation of these materials into horseshoeing techniques allows for structural reform and external

reinforcement of the hoof, with potential benefits in both therapeutic shoeing and performance enhancement of the equine athlete.

ADHESIVE TYPES

Most adhesives used to bond hoofwear to hooves evolved from use in hoof reconstruction.¹ Important features include impact resistance, type of adhesive joint loads, speed of polymerization, heat production, surface sensitivity, and environmental compatibility.

Impact resistance is particularly important because of factors such as horse's weight, speed, and high level of cyclic loading of the feet. Adhesives that remain flexible once polymerization is complete (elastomeric adhesives) perform better than rigid adhesives with similar tensile strength characteristics. When the bonding is applied directly to the hoof wall (as opposed to bonding individual components of a shoe together), at least one surface (the hoof) is always flexible. The primary load will be in peel, for which elastomeric adhesives are preferable.

Speed of polymerization is critical because the horse needs to bear weight and ambulate immediately after shoeing. The cure profile of an adhesive involves a "green" phase when the adhesive has solidified but not reached full strength. Challenging the bond in the early portion of the green phase can cause irreversible bond line failure. However, very fast polymerization may be at the expense of reduced impact strength.

The polymerization reaction produces heat that increases with the speed of the reaction. It is surface area dependent for a given volume of polymer. In concentrated volumes that are not allowed sufficient surface area to dissipate heat, temperatures can exceed 120° C in volumes typically used for hoof reconstruction or bonded shoes. Spreading the adhesive to provide increased surface area relative to volume allows dissipation of heat. Some adhesive manufacturers add fillers to very fast systems to dissipate heat, resulting in a temperature reduction of as much as 25%. Submural temperatures underlying reacting exothermic resins vary depending on the hoof wall thickness but generally do not achieve dangerous levels. However, dermal layers underlying thin hoof walls (such as those found at the quarters or in foals) may be at risk for substantial thermal trauma.

Surface sensitivity affects the ability of an adhesive to bond to a contaminated surface. Adhesives that solvate surface contaminants into the bond line are preferable. The adhesive must be resistant to moisture and microbial degradation. The adhesives commonly used for hoof reconstruction and bonded shoes are polymethyl or cyclohexyl methacrylate, cyanoacrylate, polyurethane, and, to a far lesser extent, epoxy resins. Each has distinct advantages.

Polymethyl methacrylate (PMMA) or cyclohexyl methacrylate (CHMA) systems are commonly referred to as *acrylic* adhesives. The newest elastomeric acrylic adhesives offer good impact resistance, rapid cure, minimal surface sensitivity, and excellent wetting characteristics for hoof wall and other substrates commonly used with hoof care applications. However, they have an intense odor, relatively high exothermic temperatures, and a high vapor pressure that limits shelf life in opened containers. As with

all elastomeric adhesives subjected to high peel loads, the acrylic adhesives should be used with a thick bond line.

Polyurethane adhesives produce low-modulus adhesive joints. These joints exhibit excellent impact strength and perform remarkably well under high cyclic loads. Polyurethane has the best abrasion resistance and shock attenuation of all the adhesives commonly used. However, these adhesives require extensive substrate cleaning and preparation to ensure good bonds, which are often beyond the scope of practical field applications. These adhesives also do not form effective bonds with many of the plastics commonly used with hoof care, including acrylonitrile butadiene styrene (ABS), polyvinyl chloride (PVC), and acrylic-PVC copolymers.

Thermoplastic adhesives are principally dependent on mechanical bonding for adhesion, limiting structural use in horses. Cyanoacrylate adhesives are thermoplastic, single-component systems that are cure inhibited through acid stabilization. Ambient surface moisture increases constituent pH and allows the polymerization process to begin. The principal advantage of these adhesives is the ability to form bonds with substrates that are difficult to bond for most adhesives. Cyanoacrylates are the only adhesive for many types of glue-on shoes that have polyurethane as a structural bonding substrate. They have excellent strength when loaded in shear, but poor peel and impact strength. Cyanoacrylate adhesives also are highly susceptible to post-cure moisture degradation. Because cyanoacrylates become rigid after curing, the bond line rapidly develops a "mosaic" fracture pattern when exposed to impact. This allows capillary intrusion of water into the bond line, further subjecting the bond to environmental degradation. They also have limited gap-filling characteristics. The ideal surface for successful cyanoacrylate bonding is a virtually polished surface. The bond line must be very thin.

Epoxy resins offer excellent environmental resistance, have very good shear characteristics, and are the adhesive of choice when assembling shoe components that involve engineered fabric lay-ups and when an extended or elevated temperature curing is acceptable. These systems are not useful when bonding directly to the hoof wall, because the hardeners that are commonly used markedly increase the rigidity of the cured polymer. Polyester resins have some value in cosmetic repair of hoof wall, but they lack tensile strength and environmental resistance and have limited use.

GLUE-ON HORSESHOES

Currently four principal types of glue-on shoes are available. These include the "direct-glue" method using PMMA or CHMA adhesive, the molded polyurethane "tab type" shoes that use a cyanoacrylate adhesive, the flock-lined plastic cuff that uses an epoxy adhesive, and the fabric cuff that uses a PMMA or CHMA adhesive.

Two techniques have been used for direct-glue shoes. The first method involves the use of a PMMA or CHMA adhesive without fillers, with the bond line between the distal aspect of the hoof wall and the shoe.² The hoof side of the shoe is cleaned and sanded. The hoof is prepared by cleaning the dirt and loose debris from the wall and sole. The adhesive then is applied directly to the shoe and hoof, and the shoe is positioned on the hoof so that the bond

line is continuous between each bulb of the heel and incorporates an increasing percentage of the sole toward the heel. The hoof must be held non-weight bearing through the green phase of the adhesive cure cycle, approximately 3 to 5 minutes depending on ambient temperature. Given the extended cure profile of this type of adhesive, the bond should be challenged as little as possible for 12 hours. A modification of this system has been developed using staple fiberglass fibers as a filler for the adhesive.³ The primary disadvantages are the need to keep the hoof non-weight bearing until the adhesive has green cycled and the need to bond the heel securely to the shoe.

Polyurethane "tab type" shoes use a cyanoacrylate adhesive to bond a component of the shoe (the polyurethane tab) to the hoof wall. These shoes require careful substrate preparation, including solvent cleaning and finish sanding with extremely fine sandpaper. Because cyanoacrylates have limited gap-filling properties, the prepared hoof wall must match the profile of the tab precisely. These adhesives have limited moisture and impact resistance, so shoe retention for competitive horses may prove difficult.

Plastic flock-line cuffs (Dalric Glue on Shoes, Advance Equine, Versailles, Kentucky, United States) are not actually shoes, but they act as a conjoining device to attach shoes to the dorsal aspect of the hoof wall. These devices use an epoxy (or a PMMA or CHMA adhesive) to attach the shoe to the hoof wall through a mechanical lock of the adhesive to the flock lining and rivets to attach the shoe to the cuff. This system is considerably more robust than the polyurethane tab system described previously. However, fitting the cuff to oddly configured hooves can be difficult.

The fabric cuff (Sigafos Series Adhesive Bonded Shoes, Sound Horse Technologies, Unionville, Pennsylvania, United States) system uses a PMMA or CHMA adhesive to bond a braided fabric cuff that is an integral part of the shoe to the dorsal aspect of the hoof wall. This system comes as a fully assembled shoe (Series One) or a modular system (Series Two) that allows the farrier to assemble any type of pattern configuration desired. The use of the Sigafos Series shoe has been shown to reduce distortion of the dorsal aspect of the hoof when used continually over an extended period of time when compared with nail-on shoes.¹ The primary disadvantage of this system is the limited choice of types of shoes currently available in the Series One system.

Glue-on shoes offer distinct advantages over mechanically attached shoes because of the noninvasive and non-destructive nature of the attachment. They are expensive, but this cost usually is recouped if the actual cost of lost shoes and the resultant hoof loss are considered. If the widespread acceptance of adhesives in other industries is any reflection on the potential for their use in the farrier industry, adhesives will become the dominant method of attachment of shoes for horses in the foreseeable future.

Many maladies of the equine hoof—from laminitis to hoof abscesses to quarter cracks—are complicated by a loss of integrity to the hoof capsule. Traumatic incidents such as the loss of a shoe can result in an interruption to the training or performance of an equine athlete. Although it is impossible to replace the exact characteristics of a compromised hoof, advances in reconstruction techniques have proven invaluable in both therapeutic horseshoeing as well as in prevention of secondary traumatic injuries

associated with loss of hoof. Hoof capsule distortion has been identified as a precursor to lameness, and the ability to externally reinforce the hoof through glue-on shoes, adhesives, and composite materials has been shown to reduce distortion of the hoof.

HOOF WALL RECONSTRUCTION

Traditionally, the repair of hoof defects has been accomplished through invasive stabilizing methods, such as drilling into healthy hoof around a quarter crack and lacing the disjointed hoof together with stainless steel wire. PMMA and CHMA have been used to accomplish the same result without further invasion of the hoof through the external buildup of material on either side of a defect, and the subsequent lacing through the adhesive rather than through the hoof wall. External methods provide the same level of stabilization as the invasive method.

A limiting factor in any wire technique is that the resulting stabilization is achieved only in tension as the defect is pulled together. Predicting the forces exerted on a hoof capsule is difficult, as each foot deforms under loading forces in a unique manner. Some defects are in compression instead of tension, and various shear forces

are also exerted. The adhesion of solid metal plates provides better overall mechanical stabilization of a defect; however, these repairs are often difficult to conform to the hoof and are bulky in design. The use of fabrics saturated in adhesives has provided an alternative method of hoof wall reconstruction, affording a lightweight stabilization of the hoof to various directional forces while easily conforming to the shape of the hoof.

Composite Materials and Hoof Repairs

In considering the structural capacity of adhesives, an analogy can be made to concrete. By itself, concrete has limited structural strength, but the structural capacity is greatly increased through the incorporation of metal rebar. In much the same way, the incorporation of fabrics into adhesives greatly increases the structural capacity of hoof wall repairs. Carbon fiber resists compression very well, and Kevlar is excellent at resisting tensile forces. Ultra-high-molecular weight fabrics (such as Spectra) impart excellent abrasion resistance to a repair. Liquid crystal polymers such as Vectran impart lesser characteristics of all three materials.

The orientation and weave of the fabric should also be considered in the design of a repair, because the optimal

TABLE 27-1

<i>Fabric Characteristics for Hoof Repairs</i>						
FABRIC	ADHESION	WEAR	TENSILE	IMPACT	BENDING	RECOMMENDED FOR THESE TYPES OF REPAIRS
Fiberglass	4	2	1	1	1	None
Carbon fiber	4	2	4	2	1	Repair of extremely palmar heel cracks; additional reinforcement (when used with other fabrics) for repairs in very large or active horses. This fabric should never be used when tight bends are required. Care must always be used when grinding carbon fiber as the dust is hazardous to breathe.
Polyester	4	3	3	4	4	Recommended for most repairs. Very good (even when used alone) for most types of horses.
Kevlar	3	2	4	4	3	Excellent reinforcement for carbon fiber (markedly improves impact resistance of repairs). Good to use in heavy horses such as draft horses. Repairs done with Kevlar should be covered with polyester or Spectra in highly abrasive environments.
Spectra	1	4	4	4	4	Because of poor adhesion, Spectra should be used only for added abrasion resistance, as the outermost layer over other fabrics in extremely abrasive environments.
Vectran	3	3	4	4	3	Vectran is in the same chemical family as Kevlar, with somewhat higher abrasion resistance.
Kevlar-carbon fiber hybrid (Cobrasox)	3-4	2	4	4	2	Good for repairs on heavy horses when tight bends are not required. Repairs done with Cobrasox should be covered with polyester or Spectra in highly abrasive environments.
Vectran-polyester hybrid	3-4	3-4	3	4	3-4	Excellent replacement for polyester for highly competitive horses or heavy horses. Somewhat better abrasion resistance than Kevlar or Cobrasox.
Carbon fiber-fiberglass hybrid	4	2	3	1-2	1	None

Key: 1 = poor, 4 = best. (Values are only comparative to the nine materials listed and are subjective.)

structural plane is along the directional plane of the fibers.

The most commonly used adhesives (PMMAs and urethanes) are exothermic, with a total energy release that is dependent on the quantity and thickness of the repair. The temperature at the surface of the foot is approximately 50° C, with an increase of 4 to 7° C in the dermal tissues, depending on the type of adhesive used and the thickness of both the repair and the hoof wall. Any adhesive composite repair should avoid direct contact with the dermal tissues of the hoof to avoid thermal damage. To avoid bacterial or fungal infection, an inert material, such as polystyrene foam, modeling clay, or silicone molding material, is required to separate the composite repair from the dermal tissues.

There are several considerations when choosing which fabric to use for repairing a hoof. These include adhesion,* wear resistance,[†] tensile strength, impact resistance, and bending.[‡] The types of materials commonly used for fabric hoof repairs include fiberglass, polyester, carbon fiber (care must be used when grinding or rasping carbon fiber because the dust is hazardous to breathe), Kevlar, Spectra, and Vectran (Table 27-1).

Other considerations include the weave pattern and thread count. *Basket weave* is the simplest and least expensive type of weave available for most types of repair fabrics.

*The adhesion of the hoof repair adhesive to the fabric.

†The resistance of the fabric (bonded to the hoof with hoof-repair adhesive) to abrasion from ground surfaces such as sand as well as resistance to abrasion from the opposite foot.

‡Some types of repair require the fabric to bend tightly around the hoof wall (such as when the fabric is wrapped around the heel) or an appliance (such as a wire when doing a fabric-reinforced wire suture repair).

It is important to realize, however, that the cost of any of the fabrics is minimal given the small amount used for each repair. However, the basket weave has the poorest “drape” characteristics (the ability of a fabric to wrap around and conform to different shapes).

Braid has significantly better handling and drape characteristics at a slightly higher cost.

Nonwoven roving is a type of fabric usually supplied in a “tape”[§] form. It is not woven. Instead, all the yarns lie parallel to one another and are lightly stitched together every few centimeters. For any given type of fabric material, the nonwoven roving is the strongest in tensile strength. Nonwoven roving (particularly carbon fiber nonwoven roving) is excellent for repairs where a great deal of strength is needed and where very little repair area is available, such as extremely caudal heel repairs. However, the drape with nonwoven roving fabrics tends to be rather poor.

Thread count refers to the number of threads per linear inch, and is sometimes called the *pick*. Tighter thread counts (i.e., more threads per inch) tend to be more abrasion and snag resistant. Lower thread counts tend to have better drape characteristics. An important consideration with hoof repair fabrics is that the adhesives typically used with hoof repair tend to have high viscosity and are difficult to saturate into many fabrics. As a result, thread counts higher than 17 threads per inch should be avoided for hoof repair.

§The term *tape* (when referring to fabrics) means that the fabric is supplied in a long, narrow (usually less than 8-inch-wide) strip. Unlike other types of tape, there is no pressure-sensitive material applied to these fabric tapes.

Chapter 28

Trauma to the Sole and Wall

Robin M. Dabareiner, William A. Moyer, and
G. Kent Carter

PROBLEMS ASSOCIATED WITH HORSESHOE NAILS

Nail Bind

History and Clinical Signs

A *close nail* or *nail bind* refers to placement of a horseshoe nail not necessarily in the sensitive structures of the hoof, but close enough that the nail exerts sufficient pressure on these structures to cause discomfort. A horseshoe nail is designed to be driven obliquely through the hoof wall. When the nail is driven, the tip is placed at the inner edge of the white line with the bevel of the nail tip facing inward. When driven, the bevel contacts the hard hoof wall and curves outward and exits 1 to 2 cm above the level

of the shoe. The tip of the nail is removed and the remainder is bent over to form a clinch to hold the shoe firmly to the hoof. Correct nail placement is important because if the nail is placed too shallow (superficial), the hoof wall will weaken and possibly split; if it is placed in too far, the sensitive structures of the hoof may be entered (pricked) (Figure 28-1). Overzealous clinching of the nails causes inward bending of the nail that can result in pressure on sensitive tissues, which may result in immediate or delayed pain and lameness. Slight displacement of a shoe also can result in nail pressure on sensitive tissues.

Diagnosis

Diagnosis of nail bind is difficult and often determined by eliminating other causes of foot pain. Lameness varies from subtle to severe. Sometimes a horse exhibits a change or lack in performance. The problem may not arise until several days after shoeing. Sometimes a horse is sound when trotted in a straight line, but it shows lameness when pulled in a tight circle or when it makes a turn. It is important to realize that nail bind is not always associated with poor farriery. A good nail can become a problem nail days or weeks after shoeing if the shoe shifts, causing abnormal nail pressure, or if the horse had a poor-quality hoof wall and hoof wall loss occurs. This is a common problem in Thoroughbred (TB) racehorses and usually involves the medial heel nail (the medial quarter and heel wall usually is the thinnest

Fig. 28-1 • Schematic of ideal, close, and pricked (quickened) horseshoe nail placement.

aspect of the hoof wall). Hoof tester evaluation using both pressure and percussion on the outer hoof wall capsule may cause a painful response over the offending nail. Heat and increased digital pulse amplitudes may not be present, depending on the duration of the close nail. Often diagnosis is determined by pulling single nails one by one from the shoe and evaluating the horse for lameness after each nail is removed. Paradoxically, lameness is sometimes transiently accentuated after removal of the offending nail.

Treatment and Prognosis

The treatment of nail bind is removal of the offending nail; usually lameness resolves within a few days. The empty nail hole may be flushed with a disinfectant solution, such as dilute povidone-iodine solution, dimethyl sulfoxide, or an antiseptic solution such as thimerosal (Merthiolate, Eli Lilly, Chicago, United States). No additional treatment is usually needed. Prognosis is good once the nail has been removed, provided infection does not ensue.

Nail Prick

History and Clinical Signs

Nail prick or *quicking* refers to penetration of the sensitive hoof structures, usually the sensitive laminae, by a driven horseshoe nail (see Figure 28-1). The horse usually reacts as the farrier drives or clinches the nail by jerking the foot from the farrier.¹ Sometimes blood appears on the nail or leaks from the nail hole. Nail pricks occur for many reasons and are not always caused by a misdirected nail. Poorly made shoes, misdirected nails, selection of a nail that is too large, poorly placed nail holes, and faulty nails can result in a nail prick. Horses with poor hoof quality, thin hoof walls, or flaring hoof walls can be very difficult to nail and thus are at greatest risk. Fractious horses and young horses that have not been previously shod may lean on the farrier or repeatedly pull the foot from the farrier, making driving a nail difficult. A rushed farrier predisposes to nail pricking, but it can also happen to the best of farriers. Damage from an improperly driven nail can vary from minimal to serious infection.

Diagnosis

Diagnosis of a misdirected nail warrants great diplomacy from the veterinarian, because many owners become unjustifiably upset with the farrier. Some horses repeatedly stomp the affected foot or paw the ground immediately after shoeing. Others point the affected limb after shoeing.

Lameness may not be apparent immediately but may occur days after shoeing when the nail hole becomes infected and the trapped pus begins to exert pressure. The horse usually becomes acutely lame, and the lameness worsens over time unless it is treated. An infection may migrate up the lamellae (white line) and create an abscess or soft spot at the hairline of the coronary band. The abscess is directly aligned with the hoof wall tubules leading to the infected nail hole, which is an important diagnostic aid. Hoof tester examination, using both pressure and percussion over each nail, is essential to locate the offending nail. Increased digital pulse amplitudes and heat may be present.

Treatment

Pricks from nails can be potentially serious and require immediate treatment. If the nail prick is discovered by the farrier at the time of shoeing, the nail is removed. The nail should be examined for moisture or blood. The nail hole can be irrigated with dimethyl sulfoxide, povidone-iodine solution, or hydrogen peroxide. The nail hole is packed with iodine-soaked cotton and left open. Often the nail is redirected and no further treatment is needed. Tetanus prophylaxis is essential for an unvaccinated horse.

If the offending nail cannot be localized or the nail hole is infected, the shoe is removed. Hoof testers then are used to localize the painful nail hole. Many times the pressure from the hoof testers causes black, malodorous liquid exudate to exit from the hole. This may not be obvious immediately, but if the foot is replaced to the ground and the horse walks a few steps, exudate may become obvious. The basis of treatment is to establish drainage. The infected nail hole often requires enlargement with a loop hoof knife or curette. Ideally a cone-shaped hole is made, with the larger opening at the bottom of the hoof. The hole is irrigated or the entire foot is soaked in an Epsom salt and povidone-iodine foot bath for 20 to 30 minutes twice daily until the infection is resolved. It is important to protect the foot from the environment (mud, dirt) by keeping the foot bandaged between foot soaks. Alternatively, a poultice can be applied to the foot for several days. Additional medications usually are not necessary unless infection is widespread. Antiinflammatory medication may be beneficial to decrease pain. Once the infection has cleared, the shoe is replaced. The affected nail hole can be packed with iodine-soaked cotton, and the horse reshod with a plastic pad covering the sole. Alternately, a hole can be drilled into the shoe over the affected nail hole and the shoe can be replaced, leaving access to the infected area for daily irrigation and povidone-iodine packing.

Prognosis

Prognosis after nail prick usually is good, provided that minimal damage occurs to vital structures of the foot. Establishing drainage for infection is important to avoid potential complications, such as infectious osteitis of the distal phalanx or infection of the distal interphalangeal (DIP) joint.

Solar Bruising

History and Etiology

A *bruise* is a contusion or impact injury that causes focal or generalized damage with subsequent hemorrhage of the

solar corium. Sole bruising occurs commonly in all types and breeds of horses, especially in racing TBs and Standard-breds (STBs).² The degree and severity of lameness vary from acute, severe lameness to chronic mild or intermittent pain, depending on location and degree of damage. It is important to determine the cause of the bruise, because this dictates proper treatment and prevention. The general cause is abnormal focal weight bearing on the solar surface of the foot. The location of the bruise is helpful in determining the cause of the injury. The most common location is the junction between the bars and the walls at the heel, termed a *corn*.³ Corns occur most frequently on the medial side of the front feet. Heel bruising may be the result of improper shoeing or trimming. Some farriers bend the medial branch of the shoe toward the frog to prevent the horse from stepping on and pulling the shoe. This shoe position causes direct pressure to the sole at the heel angle, instead of the heel wall, resulting in continued concussion and bruising. A shoe that is too small or does not extend far enough back under the heel can lead to heel bruising.⁴ The ends of the shoe should extend to the widest aspect of the frog for proper heel protection. Horses with long-toe-low-heel hoof conformation are susceptible to heel bruising. Toe bruising can be caused by excessive impact or weight bearing on the toe region secondary to another cause such as heel pain. An improperly positioned horseshoe that rests on the sole instead of the hoof wall also causes toe bruising. Horses with long toes and those shod with toe grabs concentrate impact at the toe region.⁴ Sole bruising occurs often in horses with flat feet because the sole repeatedly strikes the ground surface. A flat foot can be congenital, can be created by trimming the hoof wall too short, or can be caused by excessive wall breakage at the quarters. Thin-soled horses or excessive trimming of the sole reduce the sole protection and predispose to sole bruising. Loose shoes can shift position, and improperly balanced feet cause excessive impact forces to specific regions of the foot and cause bruising.⁴ Riding on hard and rocky ground can result in stone bruises. A shod foot that has overgrown to the point where the shoe is riding on the sole is at risk of bruising.⁴

Clinical Signs

The degree of lameness from sole bruising can change daily, and lameness varies among horses. Removal of the shoe usually increases the degree of lameness. The bruising can be acute or chronic depending on the cause. Digital pulse amplitudes are increased after exercise, and careful hoof tester evaluation often reveals a focal painful response. Discoloration is common, but if the bruise is chronic or deep or if the horse's sole is pigmented, it may be difficult to identify. Bruising often affects several feet. In most horses, lameness will improve after perineural analgesia of the palmar digital nerves. Radiological changes are rare but may include a serum pocket (fluid line) between the distal phalanx and external sole abscess. Such lesions are easier to detect with digital or computed radiography than with conventional radiography. Persistent, chronic bruising may lead to osteolytic lesions or solar margin fractures of the distal phalanx.

Treatment

Initial treatment with phenylbutazone (2.2 mg/kg bid) and soaking the feet in Epsom salts help decrease

inflammation. Corrective or proper shoeing is imperative to shift the weight-bearing forces away from the damaged area of the foot. Sole paint consisting of a combination of equal parts of phenol, iodine, and formalin can be applied to toughen the solar surface. Hoof balance problems and shoeing causes, such as heel calks, toe grabs, or tucked heels, should be eliminated. One of many different shoeing techniques then is used to decrease impact and protect the bruised area. One method is use of a rim pad that is cut out over the bruised area so that the affected heel or quarter is "floated" and thus receives minimal weight-bearing forces. Another method is application of a bar shoe with a deeply concaved solar (inner) surface to stabilize the foot and alleviate any sole pressure from the shoe itself. A wide-web shoe may provide relief by covering and providing protection over a larger surface. It is important that this shoe be properly positioned on the hoof wall so that it does not increase sole pressure. Application of full pads packed with silicone or oakum may provide temporary relief by distributing weight-bearing forces over a wider area but often leads to a weakened and softer sole, causing recurrent problems.⁵

Prognosis

The prognosis is good if the inciting cause of the bruising can be corrected. Corrections may be difficult in horses with flat feet or long-toe-low-heel conformation, and such horses often have recurrent solar bruising.

Thrush

Thrush is a bacterial infection characterized by an accumulation of black, malodorous, necrotic material, usually originating within the central or collateral sulci of the frog of the hoof. This degenerative condition may spread to involve deeper structures of the foot, such as the digital cushion, hoof wall, and heel bulb region, causing inflammation and breakdown of these structures.⁶ Many keratolytic organisms may be present, but *Fusobacterium necrophorum* is often isolated. Thrush is most often caused by poor environmental conditions; horses standing in soiled stalls, deep mud, swampy land, or wet pastures are at risk, especially if the feet are not cleaned daily.⁷ Poor hoof conformation also predisposes to thrush. Saddlebreds, Tennessee Walkers and other gaited horses, and some Warmblood breeds have long feet with naturally deep frog sulci and are at risk of thrush.⁷ Horses with a sheared heel or acquired frog deformity also are predisposed. Horses shod with full pads may develop thrush secondary to moisture and dirt collection under the pad. Other well-kept, clean horses can develop thrush for no apparent reason. Horses with severe thrush need to be differentiated from those with canker (see Chapter 125 and page 319). Lameness in horses with mild thrush is often blamed on the presence of thrush, but a careful lameness examination will reveal a primary source of pain elsewhere, coexistent with mild thrush.

Clinical Signs and Diagnosis

Lameness often is not apparent, but if present, the severity can vary. With severe thrush lameness can be obvious, but in most horses thrush is an additional finding and the primary source of pain is elsewhere. Diagnosis is based on the presence of black, malodorous discharge located most commonly within the frog sulci. The central frog sulcus

often is malformed and very deep. A painful response may occur when the affected sulci are cleaned, because the degenerative process may extend to sensitive structures of the foot. If structural damage has occurred, the bulbs of the heel may move independently of each other, causing pain on manipulation.

Treatment

The predisposing cause should be identified and, if possible, removed. The horse should be moved to a clean, dry environment, and the feet should be cleaned daily. Any necrotic debris and undermined tissue are carefully debrided and cleaned using a hoof knife. Foot bandages may be necessary if the debridement is extensive. Systemic antimicrobial drugs may be necessary if deep or more proximal tissues are affected, but infection is usually managed by topical medication. Several caustic materials have been recommended, including a combination of phenol, tincture of iodine, and 10% formalin, Kopertox solution (Fort Dodge, Fort Dodge, Iowa, United States), or methylene blue. Initially, when the frog is very sensitive, the caustic materials may be too harsh and actually cause more tissue damage. We recommend to begin treatment by trying to dry the sensitive tissue with a mixture of sugar and povidone-iodine solution; make a paste consistency and apply that over the affected area until the tissue is dry and less sensitive. Once the frog begins to harden and keratinize, then the more caustic materials can be used. Others have recommended foot soaks in chlorine bleach (30 mL of bleach in 5 L of water). Corrective trimming and farriery may be necessary. If heel instability is present, a bar shoe may be necessary to stabilize the palmar aspect of the foot. Exercise is important to strengthen the palmar aspect of the foot and will naturally clean the feet.⁷ The best treatment for thrush involves prevention by educating the client on proper hoof hygiene.

Prognosis

The prognosis for horses with thrush is favorable if the cause can be identified and eliminated and if the condition is treated before extensive hoof damage has occurred.

Sheared Heel

History and Clinical Signs

Sheared heel refers to instability between the medial and lateral bulbs of the heel. Mediolateral foot imbalance may be a predisposing cause. It is frequently but not invariably associated with distortion of the hoof capsule. The medial bulb of heel often is displaced proximally, with a steep medial wall and flaring of the lateral wall (see Figure 6-3). However, instability between the bulbs of the heel can also occur in a more normally conformed foot, and distortion of the hoof capsule as previously described is not synonymous with sheared heel. It is also important to recognize that sheared heel can be present without causing lameness, although sheared heel may be a cause of lameness.

Sheared heel may be present in one or several feet and may be associated with mild to moderate lameness. Lameness is usually worst on firm or hard footing. There may be distortion of the coronary band, which usually is higher medially. There may be a deep cleft dissecting between the medial and lateral bulbs of the heel. Sheared heel may predispose to thrush.

Diagnosis

Instability of the bulbs of the heel is detected by grasping each bulb of the heel with the left and right hands and twisting each bulb in opposite directions in a shearing motion. In a normal horse the bulbs of the heel cannot be moved independently. Considerable independent motion can be associated with pain, causing lameness. However, if the lameness is severe, another coexisting cause of lameness should be considered. Lameness associated with sheared heel is removed by perineural analgesia of the palmar digital nerves.

Treatment and Prognosis

Any mediolateral or dorsopalmar foot imbalance should be corrected. The affected foot should be floated by trimming the high heel bulb shorter than the rest of the hoof wall such that it does not bear any weight. This allows the coronary band to drop down into the correct position. The foot with the floated heel bulb should be shod with a bar shoe to provide stability to the heel region. This may need to be continued for many months, and occasionally indefinitely, until some physical attachment between the heel bulbs has become established. If the hoof capsule is distorted in shape as previously described, the medial branch of the shoe should be set slightly wide to encourage the medial wall to grow down to it and prevent it from collapsing axially. Any excess flare on the lateral wall should be removed. The prognosis is generally good.

Hoof Wall Separation (White Line Disease, Seedy Toe)

History and Clinical Signs

The white line, visible at the sole, is created by the junction of the insensitive laminae of the hoof wall and the horn of the sole. *White line disease* has historically been a term to describe the separation of the hoof wall from its laminar attachments. A crack or opening occurs within the white line, allowing a bacterial or fungal infection to invade the stratum medium, with proximity to the laminae causing cavities to develop between the laminae and outer hoof wall.⁸ Environmental conditions of either too much moisture (continuous wet pastures) or drought conditions producing excessively dry feet predispose to development of a crack or opening in the white line. Horses with poor-quality hoof walls that split or crack or those with chronic laminitis and a thickened or stretched white line in the toe region may develop white line disease. The term *seedy toe* has been used differently in North America and Europe. In North America it is most often used to describe thickened or widened white line at the toe in horses with chronic laminitis, whereas in Europe it is used to describe separation at the white line, filled with crumbly material, that is not associated with laminitis. The hoof wall separation usually is a chronic condition beginning weeks or months before veterinary advice is sought, because there usually is no associated lameness. Hard ground may exacerbate any lameness seen.

Diagnosis

The degree of lameness varies, but if severe, white line disease can cause clinical signs of pain. However, the clinician should resist the temptation to incriminate this disease

as the primary source of lameness until a thorough lameness examination has been completed. Because lameness is abolished after palmar digital analgesia or a dorsally directed ring block, this disease can easily be confused with many other conditions of the foot. Visual examination of the white line, assisted by a probing instrument, reveals a cavity with separation of outer hoof wall from the laminae. Radiological evaluation determines the full extent of hoof wall separation. Often the cavity is either dry or filled with necrotic debris, which may involve a bacterial or fungal infection. The cavity is usually not painful to probing.

Treatment

If the cavity is small (extends <2 cm proximally), placement of a cotton ball soaked in tincture of iodine in the cavity, with the shoe keeping the cotton in place, may be enough to stop the progression of the problem. However, if the cavity is extensive, then the separated outer hoof wall is removed using hoof nippers, hoof knife, and motorized tools. The aim is to remove cracks or crevices that could harbor bacteria. A Dremel tool burr (Dremel, Racine, Wisconsin, United States) is useful to smooth any cracks in the insensitive laminae that are exposed after hoof wall removal. Large defects in the hoof wall require protection. A heart bar shoe redistributes weight-bearing forces to the frog and palmar region of the foot and away from damaged and weakened areas. The hoof wall defects prevent normal nailing procedures; therefore clips or support bars (Figure 28-2) can help to secure the shoe to the hoof. After hoof wall removal the exposed laminae may still have an active infectious component. The horse should be kept in a clean, dry stall; the exposed laminae are treated topically with iodine or thimerosal (Merthiolate) daily for 10 days or until they are dry. The horse may then be a candidate for prosthetic hoof wall repair using a product such as Equilox (Equilox International, Pine Island, Minnesota, United States). The plastic acrylic is trimmed and shaped to the horse's natural hoof wall at the next shoeing. The hoof to which the acrylic is applied should be kept dry to avoid losing the acrylic patch. The horse may return to normal activity once the prosthetic patch is in place. It is very important to keep the patch dry, including preventing the horse from going out in the pasture when the morning dew is still present on the grass. The owner should be cautioned

Fig. 28-2 • Extensive hoof wall removal requiring a support bar attached to the remaining hoof capsule to secure the bar shoe to the hoof.

that 50% of prosthetic patches may result in infection and abscessation under the patch, which will necessitate removing the patch and topically treating the exposed laminae again. It can be very difficult to sterilize the exposed laminae given the horse's barn environment.

Prognosis

Prognosis depends on response to treatment and cause of the original problem. Horses with poor hoof quality or primary laminitis often have recurrence. If the horse responds to original treatment and if environmental conditions improve, prognosis is good.

Poor Hoof Wall Quality

Poor hoof quality plagues many horses. Many factors determine hoof quality, including the environment, farrier management, hoof conformation, owner management, and use of the horse. Drought conditions may result in dry, brittle hooves that are prone to hoof wall splitting, cracking, and bruising. Foot growth slows during hot, drought conditions. Excessive moisture creates a weakened hoof wall that may flatten or collapse under normal weight-bearing forces. The heel may collapse, which leads to corns and heel bruising. In addition, the weak hoof wall will not hold nails, and the hoof wall separates in layers similar to wet plywood. A muddy environment may increase the risk of development of a secondary hoof abscess. Even worse is a fluctuation of wet-dry-wet-dry environments. Four problems that contribute to the wet-dry environment require owner education. The first is the growth of spring grass that gets high. Horses that are on pasture are exposed to the morning dew on the grass (wet), then the dry heat during the days (dry), and this morning wetness and afternoon dryness cause hoof wall separation, nails that loosen, and shoes that will not stay on. The second problem occurs when horses are allowed access to a pond or stream during the hot summer months. The horse's feet are dry until they wade into the water and then get wet; this causes brittle and cracking hoof walls. Another potential problem is daily washing of the horses after exercise during the hot summer months, or if an owner lets a water trough overflow to create a mud hole for a horse to step into. The wet-dry fluctuation causes poor hoof wall quality. Improper trimming and shoeing methods can cause substantial hoof wall damage. Horseshoe nails that are placed too far outward in the hoof wall, or exit too low in the hoof wall, weaken the hoof wall and cause splitting and cracking. Many TB horses with long-toe-low-heel hoof conformation often have collapsing heels and thin, weak hoof walls that make proper nail placement and farrier management difficult. The most common cause of weak, poor-quality feet is lack of exercise and stall housing.

Diagnosis

Diagnosis is somewhat subjective, as poor hoof quality is usually in the eye of the beholder. There are no objective criteria for determining hoof quality. Diagnosis is usually made by visual examination of the foot. Communication with the farrier is imperative for the diagnosis and future treatment plan. Horses with poor hoof wall quality often have palmar foot pain or are prone to sole and heel bruising. They are prone to losing shoes, which can accentuate the problem.

Treatment

If possible, the cause of the poor hoof wall quality should be corrected if identified. In drought conditions, painting the entire hoof and coronary band daily with a lanolin-based hoof dressing is sometimes beneficial. We prefer the product Hoofmaker (www.manentail.com). In an excessively wet environment, confining the horse to a stall and avoiding standing water or wet pastures may improve hoof wall quality. Educating the owner concerning causes of wet-dry fluctuation is very important. If a horse is going to be in wet conditions, instruct the owner to paint the hoof wall with a hoof sealant to seal the moisture out of the feet. We have used a product called "Hoof Shield" (www.monet-tafarrier.com) with good success. Poor farriery can be addressed, but in many horses poor hoof conformation and poor environment are more difficult to manage. Unbalanced long-toe-low-heel hoof conformation should be corrected as much as possible with proper trimming of the heel back to the widest portion of the frog. The toe of the foot is shortened as much as possible, and a rockered, round, or square-toed shoe is used to further decrease toe length and ease breakover. Egg bar shoes are used if more heel support is needed. Access to the outdoors and being able to move about are helpful but often difficult to achieve.

Hoof quality also is a function of proper diet and exercise. The horse's nutrition should be evaluated, paying particular attention to protein quantity. Biotin supplements may be beneficial.

Prognosis

Poor hoof quality usually is not corrected but managed. Prognosis is generally unfavorable unless a specific cause can be identified and eliminated.

PENETRATING INJURIES OF THE SOLE

Subsolar Abscess

History and Clinical Signs

Subsolar abscess (gravel) is one of the most common causes of acute lameness in all horses. Subsolar abscesses may originate from a penetrating wound in the white line, nail hole, or deep subsolar bruise. A cause may not be identified. Lameness is usually acute and severe (grade 3 to 4 of 5) and may worsen over time until drainage is established. Lameness that develops during work or when a horse is turned out may falsely lead to the suspicion of a traumatic injury. The horse often points and may not bear full weight on the affected limb. Distal limb swelling often accompanies a subsolar abscess that has not drained, leading the owner to suspect tendon injury. Systemic signs of infection (fever, lethargy) may be present if deeper structures are involved. The infected tract may migrate and open at the coronary band. Before breaking open, a soft, painful area can be located by digital palpation of the coronary band.

Diagnosis

Digital pulse amplitudes are usually, but not always, increased, and the hoof capsule may have heat. A focal painful area can usually, but not always, be located with careful hoof tester examination. If the sole is extremely hard, it may be difficult to locate a subsolar abscess. Careful paring of the sole and frog may be helpful in locating the

abscess, assuming that the horn is not too hard, but the clinician must be careful not to damage good, healthy tissue while looking for the infection site. Unnecessary, aggressive paring may lead to large painful areas that take months to heal. Foot poultices and hot water foot baths with Epsom salts help to soften the horn and eventually localize the affected area, especially in horses with hard horn. Grey or black, malodorous liquid leaks from the infected tract (see Figure 6-10). Firm digital palpation of the surrounding area can help to determine the extent to which adjacent tissues are underrun. Similar clinical signs can also be seen in weak-footed TB horses, especially in the palmar aspect of the foot, associated with frank subsolar hemorrhage. Radiography sometimes is useful to identify a gas or fluid pocket (see Figure 129-1). In horses with no localizing clinical signs, it may be necessary to use local analgesic techniques to determine the site of pain causing lameness. Severe lameness associated with a subsolar abscess may be only partially improved by apparent desensitization of the foot.

Treatment

Treatment is aimed at establishing adequate drainage. If the tract is open at the sole surface, it should be enlarged just enough for good irrigation and drainage. This may require sedation or perineural analgesia of the foot. If pink tissue or blood is encountered, debridement should be discontinued. Large holes should not be used, to avoid solar corium protrusion, which can be a painful sequela to overzealous hoof paring. If drainage occurs at the level of the coronary band and solar surface, through-and-through lavage is beneficial. Debridement at the coronary band level should be minimal to prevent iatrogenic DIP joint contamination. Once drainage is established, the foot is protected from the environment and recontamination with a foot bandage or poultice. Continued foot soaks in warm water povidone-iodine and Epsom salt foot baths should be continued until infection and inflammation are eliminated. The shoe is replaced when the affected area is dry and cornified. A small cotton ball soaked in tincture of iodine is often placed in the defect before reapplication of the shoe to prevent recontamination of the site. Large areas may require a plastic pad under the shoe for solar protection. Antimicrobial drugs and nonsteroidal antiinflammatory drugs (NSAIDs) are rarely needed, unless infection is severe or deeper structures have been penetrated. Many practitioners consider antibiotics contraindicated because administration may prolong clinical signs. However, if swelling and infection of the coronary band and subcutaneous tissues of the pastern region occur, antimicrobial therapy is indicated. Because lameness can be severe in horses with this type of disseminated infection, involvement of the DIP joint is often suspected but usually not present. Tetanus prophylaxis is mandatory.

Prognosis

Prognosis in horses with a simple subsolar abscess is excellent but decreases if complications develop in which deeper structures of the foot are involved.

Deep Penetrating Injuries to the Sole

History and Clinical Signs

A horse's environment is filled with sharp objects that can penetrate the sole, causing severe damage to structures

deep within the hoof capsule. All puncture wounds should be considered potentially serious, but those in the solar white line or palmar frog area require special attention because of the potential for navicular bursa, digital flexor tendon sheath (DFTS), deep digital flexor tendon (DDFT), DIP joint, or distal phalanx involvement.

The clinical signs vary with anatomical structure involved and chronicity of the injury. Lameness may be mild at the time of injury but moderate to severe once inflammation and infection occur. Penetrating wounds of the navicular bursa or DDFT result in severe lameness and a reluctance to bear weight on the heel.

Diagnosis

If a foreign body is found in the bottom of the foot, the owner should usually be instructed to leave the object in the foot, unless there is danger of further penetration. Radiography is performed immediately to determine depth of penetration and orientation, and orthogonal images are mandatory. In many horses, little superficial evidence of penetrating injury is present. Digital pulse amplitudes are increased, and the foot is usually warm to touch. Hoof testers are useful to determine a focal point of pain, but often the entire surface of the foot is reactive. If necessary, the horse should be sedated and the foot desensitized to facilitate further examination. Light paring of the sole and frog areas with a hoof knife may reveal a black spot indicating the penetration site. Often, however, the entry is not discovered, because the elastic nature of the hoof structures causes the site of penetration to collapse. If an entry wound is discovered, the foot is scrubbed thoroughly before insertion of a sterile, flexible probe. Care must be used so that inadvertent force and horse movement do not cause the probe to penetrate previously unaffected structures. A less invasive and preferred method is to place a sterile teat cannula into the hole and inject sterile radiodense material to determine the affected structures (Figure 28-3). It is important to obtain a true lateromedial radiographic image to determine the dorsal spread of the contrast media.

If infection of the navicular bursa (see later), DIP joint, or DFTS is suspected, paracentesis, synovial fluid cytological studies, and culture and antimicrobial susceptibility tests should be performed. Comprehensive radiographic examination should be performed to assess the distal phalanx and the navicular bone. Initial radiographs may appear normal, but radiolucent defects or new bone formation may become apparent within 10 to 14 days. Magnetic resonance imaging can be extremely useful to identify the extent of soft tissue injury in the face of a known penetrating injury⁹ and to provide evidence of a previous penetrating injury in horses with lameness with no known history of such injury. The identification of a hemosiderin tract leading to an area of damaged tissues is pathognomonic.^{10,11}

Treatment

If penetration of deep hoof structures is suspected, broad-spectrum systemic antimicrobial drugs, NSAIDs, and tetanus prophylaxis should be administered. During the initial 3 to 4 days, distal limb regional limb perfusion with an antibiotic (1 g amikacin or 2 g cefotaxime diluted in 30 mL saline) is also recommended, to achieve high local tissue concentrations of antibiotics. Systemic antibiotic

Fig. 28-3 • Oblique radiographic image of a foot; radiodense contrast material has been injected into a hole through the sole, the result of a penetrating injury. The contrast media extends proximally. A lateromedial image is also required to define better which structures may be involved.

therapy usually should be continued for 2 weeks after resolution of clinical signs of infection. Establishment of drainage, copious lavage with sterile ionic fluid, and debridement of all necrotic tissue are indicated. Management of infection of the navicular bursa is discussed later (page 316).

If the DDFT is involved (infectious tendonitis), debridement and removal of frayed and infected tendon fibers may be performed in a standing, sedated horse using a tourniquet and perineural analgesia, or with the horse under general anesthesia depending on horse temperament and owner financial constraints (see later). After debridement, use of a 4- to 8-degree wedge shoe decreases forces on the DDFT and provides some pain relief. The wedge shoe angle is gradually decreased over several months as the DDF tendon begins to heal and strengthen. The bottom of the foot requires protection with a bandage or hospital plate until the surgical site granulates in and cornifies.

Infectious Osteitis of the Distal Phalanx

Deep penetrating wounds to the sole, especially the solar-white line junction, can result in infectious osteitis of the distal phalanx. Usually a chronic, recurrent draining tract is located at the coronary band or solar surface of the foot, associated with variable lameness. Infection of the distal phalanx also can result from undetected soft tissue infection, from dissection of subsolar abscesses, or as a sequela to laminitis secondary to recurrent abscessation and ischemia at the toe. As the bone infection progresses, blood supply to the area is compromised, and the area of avascular

Fig. 28-4 • Dorsoproximal-palmarodistal oblique radiographic image of the distal phalanx demonstrating infectious osteitis with a sequestrum (arrowheads).

bone separates from the parent bone, forming a sequestrum.¹² Radiological abnormalities may not be detectable for weeks after a penetrating injury.¹² Radiography reveals a radiolucent area in the margin of the distal phalanx, with or without sequestrum formation (Figure 28-4). Debridement and curettage of all soft and necrotic bone often can be performed in a standing, sedated horse, but general anesthesia may be required. The foot is desensitized using perineural analgesia, cleaned with a hoof knife and steel brush, and prepared for aseptic surgery. Hemostasis is achieved by wrapping a roll of elastic bandage firmly around the fetlock joint to compress and occlude the palmar digital arteries. The infected bone is accessed by removal of sequential layers of the sole using either a motorized Dremel tool or a Galt trephine (Miltex, Bethpage, New York, United States) with a retractable pilot bit.¹³ The infected bone usually is discolored and soft and should be curetted to healthy bone margins. Culture of the infected bone and microbial sensitivity testing should be performed. A post-operative radiograph should be obtained to ensure complete debridement. After surgery the surgical site is packed with sterile gauze sponges soaked in antiseptic or antimicrobial solutions, and then the foot is bandaged. Disposable diapers and duct tape are inexpensive materials used to make a waterproof foot bandage. The bandage is changed at 1- to 2-day intervals for the initial few weeks. A bar shoe and hospital plate provide solar protection. A plastic pad secured with duct tape also works well. The bolts and metal plate are removed from the hospital plate, and the surgery site can be cleaned and treated; the plate then is bolted back in place. After surgery the horse is confined to a small area until the hole granulates and cornifies, which usually requires 4 to 6 weeks. If granulation tissue becomes excessive at the surgery site, application of 2% tincture of iodine speeds healing. If severe infection is present, the surgery site can be packed lightly with antibiotic-impregnated beads for continued antibiotic release at the infected site. Regional limb perfusion with antibiotics may also be beneficial.

Prognosis

Prognosis depends on whether the infection is severe and chronic. Horses with acute penetrating wounds that receive

immediate and aggressive treatment have a good chance of returning to athletic use. Horses with penetration injuries that have an established infection involving the navicular bursa (see later),¹⁴ DFTS, or DIP joint have a poorer prognosis. Prognosis for horses with infectious osteitis of the distal phalanx is good if the cause of infection is not laminitis. In one study, up to 24% of the distal phalanx was removed with successful results.¹⁵

PENETRATING WOUNDS TO THE NAVICULAR BURSA (BURSA PODOTROCHLEARIS), INFECTIOUS (SEPTIC) NAVICULAR BURSITIS, "STREETNAIL"

Mike W. Ross and Sue J. Dyson

Penetration of a nail or other sharp object into the solar surface of the foot is classically referred to as "streetnail," and the historically important procedure to establish drainage of the navicular bursa is the "streetnail procedure." The term *streetnail* and the surgical procedure are largely obsolete, but the clinical significance of penetrating wounds to this region of the foot cannot be overemphasized, particularly those involving the region of the frog. Of 50 horses with puncture wounds to the hoof, only 50% of horses with wounds in the region of the frog became sound after treatment, whereas 95% of horses with puncture wounds outside the frog were sound.¹⁶ Furthermore, 35% of horses with puncture wounds to the frog were dead at the time of follow-up.¹⁶ Infectious navicular bursitis and sequelae were the most common reason for euthanasia.¹⁶ Early recognition and prompt management of horses with puncture wounds to the hoof, and specifically those involving the frog and deeper tissues such as the DDFT, navicular bursa, navicular bone, and DIP joint are equally important. Ninety-three percent of horses that received surgical management within 7 days became sound, compared with only 62% of horses that were treated after 7 days.¹⁶ Horses with infectious navicular bursitis that received surgical management within 1 week of injury had a significantly better outcome than those with delayed recognition and management (8 to 60 days after injury).¹⁴ Horses with hindlimb infectious navicular bursitis were significantly more likely to have a successful outcome than those with forelimb involvement.¹⁴ Of 38 horses with infectious navicular bursitis managed using the conventional open streetnail procedure of debridement and drainage of the navicular bursa, only 12 (31.6%) had a satisfactory outcome, but when results were carefully evaluated, five of these horses were used as broodmares, leaving only seven (18.4%) horses used for riding after injury.¹⁴ Similarly, 31.6% (six of 19 horses) of horses with infectious navicular bursitis managed with open drainage and debridement became sound enough for work.¹⁶

Because of these disappointing results the conventional surgical procedure of creating a "window" in the frog, digital cushion, and DDFT¹⁷ to establish distal drainage of the navicular bursa has largely fallen from favor and cannot be recommended. Currently, endoscopic examination of the navicular bursa and other synovial structures such as the DIP joint and DFTS, if necessary, is the procedure of choice. Endoscopic examination is less invasive, causes fewer complications, and provides superior visual appraisal

of the navicular bursa, navicular bone, and DDFT when compared with the conventional open approach. Of 16 horses with contaminated and infected navicular bursae that underwent endoscopic examination and debridement, 12 (75%) became sound, and complications such as ongoing necrosis of the DDFT seen in horses managed with the conventional streetnail procedure did not occur.¹⁸ There were fewer complications and shorter hospital stays, and horses appeared to be immediately more comfortable after surgery compared with previous reports; three horses with concurrent infection of the DIP joint were managed successfully.¹⁸

Although actual results may vary among horses and surgeons, it appears that success in managing horses with infectious navicular bursitis using minimally invasive techniques is superior to that described in the previously published results and our own experience using the conventional approach to drainage and debridement of the navicular bursa. It is important to note that early recognition and management are critical. It is also important to establish the location and depth of penetration, and a minimum of two orthogonal radiographic images are necessary, if possible with the nail or penetrating object in place. After the puncture site has been cleaned, a sterile radiodense probe can be inserted, but in some horses the depth of penetration cannot be accurately determined using this method, and there is a risk of pushing foreign material deeper into the foot. Positive contrast radiographic studies should be considered, but these may not clearly show the depth of penetration. Magnetic resonance imaging can provide rapid, accurate information about the direction and depth of penetration, the presence of foreign material, and the extent of soft tissue and osseous trauma. Synoviocentesis of the navicular bursa, DIP joint, and DFTS should be performed to determine if a deep-seated contamination or infection is present. With use of general anesthesia and aseptic technique, endoscopic examination of the involved synovial structures should then be performed. The navicular bursa and palmar surface of the navicular bone and DDFT can be evaluated endoscopically and debrided. Debridement can be performed through the original penetrating tract and by creating an additional instrument portal if necessary. Samples for bacterial culture and susceptibility testing (aerobic and anaerobic) should be collected, and the tract and frayed and damaged edges of the DDFT should be debrided. Although liberal debridement can be performed, no attempt is made to make a wide incision of the DDFT. During the procedure, lavage of the navicular bursa is performed. In thick-skinned cob-type horses direct surgical access to the navicular bursa may not be possible and entry may have to be performed via the DFTS. Thorough lavage of the DFTS is mandatory to try to prevent spread of infection. Occasionally in horses with long-standing infections and concomitant osteitis of the navicular bone, or in those in which the navicular bone was directly damaged by the original trauma, the navicular bone is curetted. If necessary the DIP joint can be evaluated, but timing of examination should be preplanned because using a contaminated endoscope after evaluating a penetrated navicular bursa to evaluate a potentially uninvolved DIP joint is contraindicated. The application of a hospital plate, use of broad-spectrum intravenous antibiotics, NSAIDs, and daily regional limb perfusion of an

aminoglycoside antibiotic are recommended. Once infection is fully resolved, medication of the navicular bursa with corticosteroids may be beneficial. Although emphasis on early management is important, we have had success in horses with long-standing infectious navicular bursitis, some with radiological evidence of osteitis and fragmentation of the navicular bone, and in horses with initially severe forelimb lameness. However, when owners are spoken to initially, a guarded prognosis for future soundness should always be given, although using this approach to management of horses with penetrating wounds into the navicular bursa and surrounding structures can lead to success. Once infection is resolved, prognosis for return to full athletic function often depends on the degree of concurrent traumatic damage to tendinous and ligamentous structures within the hoof capsule incurred at the time of original injury.

HOOF WALL CRACKS

History and Clinical Signs

Hoof wall cracks occur from improper foot balance; coronary band defects; excessive hoof growth; and thin, dry, or wet hoof walls. The horny hoof wall often fails internally before being visible on the external hoof surface.¹⁹ Central toe cracks are often associated with rotation of the distal phalanx and clubfeet. Hoof cracks are characterized by location (toe, quarter, heel, or bar), length (complete or incomplete), depth (superficial or deep), site of origin (ground surface or coronary band), and whether hemorrhage or infection is present.¹⁹ Hoof cracks are usually obvious on visual examination of the foot, except those originating at the hairline, which may be only 1 to 2 cm long and difficult to see. Lameness may be present, depending on whether the hoof crack involves the sensitive laminae and whether infection is present.

Diagnosis

Hoof wall cracks are diagnosed by visual assessment of the hoof capsule. The depth of the hoof crack, pain, and associated instability surrounding the crack are determined by careful hoof tester examination. Pain associated with a hoof crack is usually determined by digital pressure and hoof tester manipulation over the crack. Purulent material may exude during hoof tester pressure. Radiology is useful to evaluate rotation of the distal phalanx in horses with central toe cracks. Bleeding from a hoof crack after exercise indicates that the sensitive laminae are involved.

Treatment

Treatment varies with hoof crack location, depth, horse use, and presence of exposed sensitive laminae and infection. Superficial hoof cracks do not extend into laminar tissue and therefore are not painful. These may be the result of improper foot balance or basic neglect regarding trimming. Treatment involves balancing the foot and providing stability by application of a full bar shoe. If the horse is shod correctly and restricted from strenuous activity, most hoof cracks will resolve.²⁰

Treatment of horses with deeper hoof cracks varies somewhat with location of the crack. If lameness exists, diagnostic analgesia should be performed to confirm that the hoof crack is the source of pain. Careful observation of

the affected foot as the horse walks slowly often shows that the defect is unstable and actually closes and pinches the underlying sensitive laminae as the foot strikes the ground, causing pain. The hoof crack is explored and debrided with a hoof knife or motorized burr (Dremel tool) to remove all necrotic and infected tissue. Any undermined hoof wall is also removed. The area is treated for 24 to 48 hours with an antiseptic such as thimerosal (Merthiolate) or tincture of iodine until the crack is dry and free of infection. The hoof wall must be stabilized so that it can regrow. Previous recommendations have suggested grooving or burring the proximal extent of the crack, but this is rarely successful.¹⁹ Many techniques for hoof wall stabilization use a combination of frog support with a heart bar shoe and clips combined with a fiberglass patch,²⁰ drill and lace technique,¹⁹ metal plate technique, or a technique using composite hoof wall repair with acrylic materials (see Chapter 27). The heart bar shoe is essential to oppose the forces causing collapse of the crack during weight bearing. The toe must be trimmed short and squared before application of the shoe. The drill and lace technique is used if the deep crack does not extend to the coronary band, and the metal plate technique is used if it does. In the metal plate technique, two drill holes are placed 1 to 2 cm on either side of the trough directly opposite each other. Care is needed to ensure that drilling too deeply does not affect deeper hoof structures. The foot should *not* be desensitized, to allow the farrier and veterinarian to assess if there is inadvertent iatrogenic penetration of deeper tissues with the screws. One or two plates are cut that are longer than the exposed hoof crack and about 0.6 cm wide. With the foot held in a non-weight-bearing position, the metal plate is drilled and bolted in place to stabilize the crack. The hoof wall adjacent to the toe crack is trimmed shorter than the remaining hoof wall to minimize weight-bearing forces on the damaged area and decrease potential bending forces on the plate. The crack is treated for several days with thimerosal (Merthiolate) or tincture of iodine until the sensitive structures begin to cornify and infection has resolved. The hoof crack can then be filled with an acrylic material (e.g., Equilox, Equilox International, Pine Island, Minnesota, United States). Adhesion of the acrylic to the hoof wall is enhanced by sanding the hoof wall, applying acetone to dry the area, and using a hair dryer at the external hoof surface before acrylic application.

Quarter and heel hoof cracks often are incomplete, and low-heel-long-toe conformation with an underslung heel may predispose horses to develop them.¹⁹ After the crack has been debrided and infection eliminated, the foot is balanced and a heart bar shoe applied. Two holes are drilled, using a 0.24-cm drill bit, approximately 1 to 2 cm apart on either side of and parallel to the crack. The holes begin at the ground surface and extend up the hoof wall. A shoelace or synthetic multifiber suture is laced in a far-near-near-far suture pattern to stabilize the crack.¹⁹ Another technique is to trim the hoof wall behind the quarter crack shorter than the remaining hoof wall such that it does not touch the shoe while weight bearing, applying a bar shoe and stabilizing the proximal extent of the crack after it has been debrided (Figure 28-5). After the crack is dry and free of sensitive tissue and infection, it is filled with acrylic material. Readers are also referred to Chapter 27.

Fig. 28-5 • A quarter crack that has been debrided; the hoof wall on the palmar aspect of the crack has been “floated” and a plastic patch glued to the proximal extent of the crack for stability

Prognosis

The prognosis for horses with both superficial and deep hoof cracks is good, and lameness usually resolves as soon as the hoof is stabilized, but recurrence is common. Success is improved if the mechanical cause of the hoof crack can be identified and eliminated.

CORONARY BAND AND HOOF WALL LACERATIONS

History and Clinical Signs

The hoof wall is thicker and stronger at the toe region and becomes thinner through the quarters and heel, where the younger hoof has a greater moisture content.²⁰ The quarter and heel regions of the foot are susceptible to traumatic injuries. Coronary band and hoof wall lacerations usually occur from the horse catching a segment of hoof on an object as it steps down or kicking or stepping on a sharp object. Hoof avulsion injuries also can occur when the foot is entrapped between fence boards or in a cattle guard. Continued hoof imbalance, improper shoe removal, and repetitive trauma to the coronary band region result in a chronic hoof avulsion or spur—a fibrous bed of scar tissue beneath a displaced segment of hoof wall. Horses that overreach are predisposed to coronary band spurring or heel avulsion injuries. Steeplechase horses and horses racing on grass often slip and lacerate the heel region of a front foot.

Hoof avulsions are described as acute (lacerations) or chronic (repetitive trauma and spur formation) injuries. Avulsions can be complete, with total tissue loss, or incomplete in that a border of hoof remains intact. Hoof wall, coronary band, sole, distal phalanx, laminae, and the DIP joint may be involved in deep lacerations. The degree of lameness varies with duration, depth, and location of the injury. Horses with acute, superficial injuries may show mild lameness, and horses with deeper structure involvement may be non-weight bearing. If degree of lameness does not seem appropriate for severity of the laceration, the integrity of the palmar digital vein, artery, and nerve should be investigated.

Diagnosis

Diagnosis is straightforward, but involvement of deeper structures can be difficult to identify. Careful manipulation of the foot causes a painful reaction if deep structures are involved and provides valuable information regarding the integrity of the supporting hoof structures. Instability of the DIP joint may indicate the presence of collateral ligament damage. If manipulation produces a sucking noise, the DIP joint or DFTS may be involved. Before further evaluation the coronary band hair should be clipped, the outer hoof wall rasped, and the sole trimmed to eliminate any superficial contamination. The area should be scrubbed with antiseptic solution, and lavage performed. The wound then is digitally explored by the veterinarian using sterile gloves. Radiography is recommended for all deep lacerations, because fractures of the distal or middle phalanges may be present. Contrast radiographic studies may be necessary to identify openings in synovial structures. Alternately, a site far removed from the wound is clipped and prepared in a sterile manner, and the DFTS and/or DIP joint is distended with sterile saline to determine if it communicates with the laceration. Ultrasonographic examination may help to determine the extent of soft tissue damage. Bear in mind that foreign material such as wood may become trapped axial to the hoof wall, and such material may be inapparent on radiographs. The DIP joint was the most common synovial structure involved in a recent study of 101 heel bulb lacerations.²¹

Treatment

The equine foot heals primarily by epithelialization and reformation of the corium.²² Decreasing motion at the affected site and hoof stabilization are essential for a successful outcome. Treatment varies with duration, severity, and type of injury. Incomplete, superficial hoof wall lacerations without coronary band involvement are treated by excision of the separated hoof wall and bar shoe application until healing occurs. The goal of shoeing is to eliminate weight-bearing forces at the damaged site and provide hoof stability.

Horses with incomplete, clean, acute hoof avulsions involving the coronary band can be treated by cleaning and debriding the displaced flap of tissue and suturing it back in place. This generally requires general anesthesia. Interrupted vertical mattress sutures with No. 1 or No. 2 monofilament suture are recommended.^{21,22} Any undermined or contaminated hoof wall is removed. Immobilization is essential and is provided by applying a foot cast. The cast is usually left in place for 2 to 3 weeks. When applying the foot cast, the clinician should ensure that the proximal extent of the cast is located at midpastern level and does not impinge on the fetlock joint during movement. Administration of systemic antimicrobial drugs and NSAIDs may be necessary if contamination of deeper structures is suspected. If deeper structures are involved, cast application should be delayed until infection is eliminated. Open synovial structures can be lavaged daily, and the foot is protected with a sterile foot bandage. Antibiotic-impregnated beads and regional limb perfusion with antibiotics may be necessary with severe contamination.

Horses with complete avulsion injuries that appear stable during movement are treated by daily cleaning and bandaging until healing occurs. Bar shoe application is required if the hoof is unstable and contaminated. A foot cast can be used if infection is not a problem.

Repair of a chronic avulsion injury, or spur, usually requires surgical excision with the horse under general anesthesia. The hoof is rasped and prepared for aseptic surgery. The hoof wall distal to the avulsed segment should be thinned with a rasp to allow placement of the sutures through the hoof wall. The excessive cornified tissue growing from the displaced coronary band is trimmed to a level just distal to the coronary band. The fibrous tissue under the avulsed segment, which lies in the bed of the defect created by the hoof avulsion, is resected. This provides a vascularized area and room for replacement of the avulsed segment back to its original location. The displaced coronary band and hoof wall are replaced and sutured in the correct anatomical position using No. 2 monofilament suture in a simple interrupted or vertical mattress suture pattern. The surgery sites are covered with a light bandage, and the foot is immobilized in a foot cast for 2 weeks.

Prognosis

Treatment is usually prolonged and often takes 3 to 5 months for complete healing, which can be costly to the owner.²² Incomplete superficial avulsion injuries or injuries that can be sutured usually heal by first intention, with a good functional, and sometimes cosmetic, end result. A roughened or thickened hoof wall distal to the defect often occurs at the site of avulsion, but it usually does not create a clinical problem. Prognosis decreases if deeper structures or synovial structures are involved. Complications such as infectious arthritis, fractures, and potential osteoarthritis can occur often with a guarded prognosis. In a retrospective study involving 101 horses sustaining a heel bulb laceration, 90% survived but 18% developed a hoof wall defect.²¹

CANKER

Mike W. Ross and Sue J. Dyson

Canker, a proliferative pododermatitis of the frog that may extend to undermine the sole and heel bulbs, is common in draft horses (and is discussed in detail in Chapter 125) but occurs in light horses as well. Differentiating this form of infection from the more common infection, thrush, is important. Canker is characterized by a foul odor (necrotic) and the presence of granulation-like tissue that bleeds easily when manipulated (see Figure 125-5). The principles of management are debriding, using a hospital plate and packing to maintain pressure on the healing solar wound, keeping the area clean, and applying topical antiseptic solutions or antimicrobial agents such as metronidazole (see Chapter 125). Alternatively, 53 of 54 horses with canker and in which long-term follow-up information was available were successfully managed using liberal debridement, topical cryotherapy, and the application of benzoyl peroxide on packing under a hospital plate.²³

Chapter 29

Functional Anatomy of the Palmar Aspect of the Foot

Robert M. Bowker

The palmar portion of the foot consists of several important structures functioning to support the foot and the limb of the horse, as well as being an integral part of the energy dissipation mechanisms present within each limb. These palmar foot structures include the cartilages of the foot (also called the *lateral collateral* or *ungual* cartilages), the digital cushion, the frog, and an extensive vascular network. Although each of these structures is present in every foot, morphological features and tissue composition vary widely among horses, which may be responsible for differing efficiencies in ability to dissipate energy. Furthermore, such differences may in part account for differences between the feet of a sound horse and the feet of a horse with chronic lameness associated with the foot. Awareness of how these tissues interact and relate to one another during foot impact is important for understanding how the foot dissipates energy and how potential problems may arise to produce lameness when energy dissipation is not efficient and the concussive forces are transmitted to the bones and other connective tissues. The domestic horse spends considerable time standing, so the structure of the palmar aspect of the foot is important for support to the weight of the horse shifted dorsally toward the connective tissues at the toe of the foot.

The medial and lateral cartilages of the foot extend from the palmar surface of the distal phalanx to the bulbs of the heel as large vertical sheets, whereas the digital cushion lies between the medial and lateral cartilages of the foot and extends dorsally toward the solar surface of the distal phalanx distal to the deep digital flexor tendon (DDFT). Associated with each cartilage of the foot is a venous network that connects with the venous vessels under the distal phalanx and the vessels associated with the dermis of the hoof wall. The venous microvasculature forms a hydraulic system that is hypothesized to provide the mechanism for how the ground impact energies are dissipated, before these forces are transmitted to and damage the bone and other connective tissues within the foot. Horses with good or excellent hydraulic systems should be more efficient in dissipating the impact energy compared with horses with feet with less-well-developed hydraulic networks.

The cartilages of the foot lie beneath the skin and dermis and the coronary venous plexus and have previously been described as rhomboid-shaped, with a convex surface abaxially and a concave surface axially. Several ligaments secure the cartilages of the foot to the digital

bones.¹⁻⁴ However, these descriptions are overly simplistic and appear to have been obtained from examination of horses with underdeveloped structures of the palmar aspect of the foot. The morphological features of the cartilages of the foot vary greatly, with a range of shapes and thickness, the presence of an axial projection from its distal edge, and the extent of vascularity.⁵ The structure of the cartilages of the foot is best determined by viewing the foot in transverse sections (Figures 29-1 and 29-2). In frontal (dorsal)

Fig. 29-2 • Transverse section of the foot of a horse with chronic foot pain with thin cartilages of the foot (arrows). The digital cushion is primarily composed of fat and elastic tissue, with little fibrocartilage.

sections cut perpendicular to the ground, beginning at the bulbs of the heel, the cartilages of the foot have a C- to L-shaped configuration. Both the upright and the base parts of the L-shaped cartilage vary in thickness among horses. The mean thickness of the upright part at the level of the navicular bone ranges from 0.5 to 2.0 cm in an adult horse (450 to 550 kg body weight). The base part or axial projection of the L-shaped cartilage varies in its thickness and the distance that it extends toward the midline of the foot overlying the bars and the frog. The cartilages of the foot are thinnest in the heel region (0.45 to 1.3 cm) but become thicker closer to the distal phalanx (0.6 to 1.5 cm) and thin slightly as they attach onto the distal phalanx (0.5 to 1.0 cm). The cartilages of the foot are thicker in forelimbs than hindlimbs.

Overlying the abaxial surface of the cartilages of the foot are a plexus, the laminar dermis, and the hoof. Loose connective tissue extends from each cartilage to the DDFT. On the axial surface the axial projection of the cartilage extends toward the midline of the foot. In most feet, this axial projection extends from the dorsal half of the cartilage; the palmar half of the cartilage has virtually no, or very small, extension into the substance of the digital cushion. However, in some feet it extends the entire dorsal-palmar extent of the cartilages of the foot. This axial projection extends to overlie the epidermal ridges of the bars, with many fingerlike projections extending into the substance of the digital cushion, and may extend across the midline of the palmar aspect of the foot under the digital cushion to fuse with that of the opposite side of the foot. These white bundles of fibrous and fibrocartilaginous tissues are easily discerned from the surrounding yellow elastic, adipose, and collagen fibers of the digital cushion. The relative thickness of the axial projection in a distal-proximal orientation varies. In horses younger than 4 to 5 years of age the axial projection usually is not fully developed along the entire length of the cartilage, and in young foals there is only a thin sheet of fibrous tissue.

The cartilages of the foot contain primarily hyaline cartilage, but in many horses from 4 to 5 years of age the medial border of the cartilage develops fibrocartilage. A fibrocartilaginous ligament of variable thickness develops between the cartilage and the DDFT; this is consistently larger in forelimbs than hindlimbs. In some horses the cartilages of the foot can ossify. This may be genetically controlled, but any stress on the foot, that accentuates vibration and results in higher energy forces being transmitted through the foot, may promote ossification.

Several ligamentous attachments connect the cartilages of the foot to the distal and middle phalanges, as well as to the navicular bone.^{3,4} The chondroungular ligaments attach the cartilage to the distal phalanx along the palmar process, whereas the medial and lateral chondrocoronal ligaments attach the cartilage to the proximal half of the middle phalanx. The medial and lateral ligaments of the cartilages of the foot (collateral chondroungular ligaments) attach the cartilage to the angle of the distal phalanx. The paired chondrosesamoidean ligaments attach the axial surface of the cartilage to the navicular bone. A pair of elastic ligaments extends between the proximal phalanx and the proximal surface of the cartilages of the foot; these ligaments are most prominent in larger horses, such as draft breeds. Cruciate ligaments of the cartilages of the foot

(cruciate chondroungular ligaments) connect the axial surface of the cartilage to the palmar process on the opposite side of the foot. Within the digital cushion are fiber tracts radiating from the connective tissue ventral to the attachment of the DDFT (digital torus), through the digital cushion, to the axial surface of the cartilages of the foot.

Each hoof cartilage is perforated by numerous vascular foramina, the number of which varies depending on the thickness of the cartilages of the foot. Within the vascular channels is a large central vein, with a rich network of microvessels termed *veno-venoanastomoses*.⁵⁻⁷ These microvessels exit the large central vein and, after a variable course within the vascular channels, reenter the same vein. More of the vascular channels are present at the distal level of the cartilages of the foot, but in feet with relatively thicker cartilages of the foot, there are more vascular channels proximally compared with feet with much thinner cartilages. The veins coalesce proximal to the cartilage into a venous plexus before uniting to form the medial and lateral palmar digital veins.^{7,8}

DIGITAL CUSHION

The digital cushion consists of a meshwork of collagen and elastic fiber bundles, with small areas of adipose tissue, and lies between the cartilages of the foot, extending dorsally as a wedge-shaped tissue attached to the DDFT and the solar surface of the distal phalanx, near the distal attachment of the DDFT.¹⁻⁴ It overlies the frog and its dermis and the axial projection from the cartilages of the foot. Proximally and dorsally the digital cushion fuses with the distal digital annular ligament and bulges into the bulbs of the heel, which are separated superficially by a central shallow groove. Some horses have areas of fibrocartilage in the digital cushion, and, if present, these extend between the cartilages of the foot and the DDFT. Two arteries pass through the digital cushion to the area distal to the digital cushion but proximal to the axial projection of the cartilages of the foot, and then branch extensively to supply the frog.²⁻⁶ Only a few vessels ramify through the digital cushion from these two arteries.

ENERGY DISSIPATION

The function of the digital cushion is controversial. The structural organization of the cartilages of the foot, the digital cushion, and the vasculature suggests a role in energy dissipation.⁵ The pressure theory suggests that at ground contact the frog stay is pushed upward into the digital cushion, forcing the cartilages of the foot outward. The depression theory emphasizes a downward movement of the pastern into the digital cushion during ground impact, forcing the cartilages of the foot to move outward. However, neither theory is consistent with measurement of negative pressure within the digital cushion during stance and locomotion.⁹ The hemodynamic hypothesis provides a hydraulic mechanism during ground contact, so that impact energy is transmitted to the fluid within the blood vessels.⁵ During ground impact the outward expansion of the cartilages of the foot probably occurs through

the bars contacting the axial projections and the downward movement of the bony column within the hoof capsule. This creates a negative pressure within the digital cushion. At this brief moment of impact the venous blood within the vessels of the palmar aspect of the foot is forced into the microvenous vasculature within the vascular channels of the cartilages of the foot. Hydraulic resistance to flow through the microvasculature dissipates the high-frequency energy waves, which are potentially deleterious to bone and other tissues. Negative pressure in the foot enables refilling of the vasculature before the next footfall. In feet with thick cartilages of the foot, enclosing more microvessels within the vascular channels, more energy is dissipated on ground contact compared with feet with thin cartilages of the foot. The fibrocartilage content of the digital cushion also is crucial to energy dissipation, because the fibrocartilage has its own energy-absorbing mechanisms. The elastic tissue acts only like a spring and absorbs little energy on ground contact, serving to return the foot to its original position as the foot leaves the ground.

The shape of the foot appears to influence the development of the cartilages of the foot and the structure of the digital cushion. In well-balanced feet, with the frog on the ground along with the bars, cartilages of the foot tend to be thick with fibrocartilage in the digital cushion.⁵ In feet with a low heel and long toe, the site of ground contact of the hoof wall at the angle of the wall and the bars usually is beneath the bony part of the distal phalanx rather than underneath the cartilages of the foot. Therefore more of the energy of impact is transferred to the bone and hoof wall laminae, as the cartilages of the foot and the digital cushion are in essence bypassed during ground impact.

NAVICULAR SUSPENSORY APPARATUS

The navicular suspensory apparatus consists of several ligaments functioning to suspend the distal sesamoid bone (navicular bone) on the palmar surface of the distal interphalangeal (DIP) joint.¹⁻⁴ Proximally, paired collateral suspensory ligaments of the navicular bone (or the collateral sesamoidean ligament) arise from the distal surface of the proximal phalanx and pass in a distopalmar direction, attaching along the abaxial surface of the middle phalanx,¹⁰ to insert on the extremities of the navicular bone. In addition, small branches attach to the axial surface of the cartilages of the foot and the distal phalanx. The attachment along the middle phalanx is important biomechanically during forward movement of the limb, because high loads are created on the joint surfaces between the navicular bone and the middle phalanx and between the navicular bone and the distal phalanx.¹¹ These ligaments are composed of collagen fibers with an abundance of elastic tissue fibers. Distally the distal sesamoidean impar ligament extends from the distal border of the navicular bone to the entire flexor surface of the distal phalanx adjacent to the insertion of the DDFT.¹⁻⁴ At its insertion the distal sesamoidean impar ligament contains an extensive network of microvessels containing arteriovenous complexes and nerve fibers within loose connective tissue septae.¹⁰ The arteriovenous complexes are innervated by many peptidergic nerve fibers, including substance P, neurokinin A, and

calcitonin gene-related peptide, which are present in the many sensory fibers innervating the foot.¹² The neuropeptides substance P and neurokinin A also have pharmacological receptors, located on the small isolated microvessels and the arteriovenous complexes within the distal sesamoidean impar ligament, to control blood flow through this intricate vascular network. When these peptides are released from the sensory nerve fibers in the foot, they promote an active vasodilatation of these small vessels, presumably through a nitric oxide pathway. The locations of these arteriovenous complexes suggest that they may have two possible functions, including providing a protective mechanism for detection of high-pressure differences within the region during movement, and maintaining the hydration status of the distal sesamoidean impar ligament and other nearby connective tissues for optimal function.

The distal border of the navicular bone has a narrow, elongated facet for articulation with the distal phalanx. Between this and the attachment of the distal sesamoidean impar ligament is a fossa containing foramina for blood vessels. The proximal border also has several small foramina. The dorsal articular surface of the navicular bone and the articulation between the navicular bone and the distal phalanx create a substantial palmar extension of the articular surface of the DIP joint. During extension of the DIP joint, with fixation of the foot on the ground and the movement of the body over the distal limb, the middle phalanx contacts the dorsal articular surface of the navicular bone, and the navicular bone becomes a weight-bearing structure. Loads transmitted through the navicular bone are supported by the proximal and distal suspensory ligaments. The role of the DDFT is discussed further in Chapter 32.

DISTAL INTERPHALANGEAL JOINT

The distal articular surface of the middle phalanx, the articular surface of the distal phalanx, and the articular surfaces of the navicular bone form the DIP joint. The relatively short medial and lateral collateral ligaments of the distal DIP joint arise from the distal ends of the middle phalanx to insert on the distal phalanx and the dorsal part of the cartilages of the foot. The joint capsule has a small dorsal pouch and an extensive palmar pouch, and blends with the collateral ligaments and common digital extensor tendon. The palmar pouch of the DIP joint is greatly expandable (25 to 30 mL in volume) and is subdivided into a proximal palmar pouch and a small distal palmar pouch extending between the navicular bone and the distal phalanx. In the midline the palmar pouch extends proximally beyond the two small secondary tendons of the DDFT, which attach to the distal end of the middle phalanx. The proximal palmar pouch almost surrounds the collateral sesamoidean ligaments.^{13,14} The DIP joint cavity also has several small abaxial, dorsal projecting outpouchings that are in close proximity to the sensory nerves of the medial and lateral palmar digital nerves. The DIP joint capsule therefore has a large surface area through which local anesthetic solution may diffuse. The comma-shaped navicular bursa is much smaller (approximately 3 mL in volume). Proximally it can extend over the proximal border of the navicular bone to protrude dorsally.

INNERVATION

The innervation of the equine distal forelimb is crucial to the horse because this is how the horse interacts with the environment. Thus the foot can be considered to be a neurosensory organ; touch, pressure, and proprioception, as well as nociception, are sensations conveyed in the nerves of the foot. The main innervation to the foot is via the medial and lateral palmar nerves and the medial and lateral palmar metacarpal nerves.¹⁻⁴ The distal continuations of the palmar nerves course parallel to the accompanying artery and then obliquely across the abaxial surface of the ligament of the ergot to supply most tissues of the palmar half to third of the foot (see Chapter 10). The Editors point out that, according to their clinical experience and current research results, diagnostic analgesia of the digital nerves results in analgesia of most of the foot, including the solar surface. Several small nerves branch from the medial palmar digital nerve to course with the artery of the digital cushion and to supply the palmar aspect of the foot, including the dermis of the overlying skin and frog, parts of the digital cushion, laminae of the bulbs of the heel, cartilages of the foot, and portions of the quarters. A small branch of the lateral palmar nerve may supply the ligament of the ergot. The dorsal branches of the palmar nerve continue with the palmar digital vein to innervate the dorsal aspects of the foot, including the DIP joint, the laminar and solar dermis, and the dorsal part of the cartilages of the foot. An intermediate branch from this nerve occurs in approximately a third of horses. In some horses a branch of the medial palmar metacarpal nerve supplies the coronary band. No communication occurs between the palmar metacarpal nerves and the dorsal branches of the palmar digital nerves. Variable branches occur, including one from the lateral palmar nerve in the metacarpal region extending obliquely to the coronary band, and one from the medial palmar digital nerve to the navicular bursa. In the hindlimbs an additional nerve supplies the coronary and laminar dermis of the dorsal foot, provided by the medial and lateral dorsal metatarsal nerves (terminal branches of the deep fibular nerve). Rarely branches from the plantar metatarsal nerves course under the distal ends of the second and fourth metatarsal bones to supply the dermis of the periople and coronet. The widespread distribution of these nerves provides a broad sensory and sympathetic autonomic innervation pattern to the tissues and vasculature of the foot.

The sensory nerves have many diverse functions in addition to conveying consciously perceived sensations, including touch, proprioception, and pain. The palmar digital nerves are composed of both small, unmyelinated nerves and larger, myelinated nerves in a ratio of nearly 4:1. Approximately 25% of the unmyelinated fibers are sympathetic nerves, and 75% are afferent fibers. Much of the sensory information from the foot and the activity of the sympathetic autonomic nerves is conveyed to the spinal cord through the unmyelinated fibers, which are the more slowly conducting nerve fibers. Many neurochemicals are present within the nerves including noradrenaline and adrenaline, substance P, neurokinin A, calcitonin gene-related peptide, neuropeptide Y, peptide histidine isoleucine, vasoactive intestinal peptide, and the enkephalins. These are released locally from the

peripheral processes of the sensory nerves, and the effect on surrounding tissues depends on which neurochemical(s) is emitted.

Most of these peptides have been identified in the foot, usually in close association with blood vessels and other microvasculature. Within the dorsal hoof wall the sympathetic fibers containing noradrenaline and neuropeptide Y are present along the small arterioles within the dermal laminae and form dense plexuses around the arteriovenous anastomoses.¹⁵ The same neurotransmitters are present in the navicular region, including the arteriovenous complexes.¹³ Noradrenaline and neuropeptide Y promote vasoconstriction, whereas vasoactive intestinal peptide is a prominent dilator of the smooth muscle of the microvessels.¹⁶ The other peptides, such as substance P, calcitonin gene-related peptide, and peptide histidine isoleucine, are present in the sensory nerve fibers of the dorsal hoof wall and the distal aspect of the distal sesamoidean impar ligament^{10,12} and also promote vasodilation by means of an endothelial-dependent mechanism and the activation of a nitric pathway.^{17,18} Activation of these sensory nerves, either directly or indirectly through pain mechanisms, produces a measurable increase in the concentration of these peptides in joints and tissues as they interact with tissue elements, such as inflammatory cells and macrophages, and controls edema formation.¹⁹

Other sensations, such as touch and proprioception, are mediated to the spinal cord through the larger myelinated fibers. The receptors of these nerve fibers are present in the bulbs of the heel and in association with the collateral sesamoidean ligaments.²⁰⁻²² The locations of these lamellated receptors appear to be critical for the perception of proprioceptive stimuli by the horse during movement when heel-first landing occurs. Activation of these receptors at ground impact and the rapid conduction to the spinal cord through these thickly myelinated fibers enable this sensory information to become incorporated into the spinal cord reflex mechanisms controlling locomotion. During toe-first or flatfooted landings, activation of these sensory receptors is presumably less. If a horse is shod with a pad, it may shorten its stride because the pacinian receptors are not adequately stimulated. If a finger-sized piece of rubber is attached temporarily to the pad, within one or two steps the stride extends forward maximally, as the horse “realizes” the importance of this area of the foot, by activation of the sensory receptors. If the rubber is removed after several days, the gait does not revert. Together the unmyelinated and the myelinated nerves enable the horse to smoothly negotiate the varying surfaces of the terrain during locomotion and provide a means for monitoring changes in the peripheral tissues and controlling the physiological and pathological environment within the foot. In addition to these pain-related sensory nerves, the foot also contains numerous myelinated nerves involved in touch and pressure sensation, permitting the horse to realize where its feet are during stance. Their importance is realized when riders of barefooted horses often remark that their horses are able to “feel” the ground surface and more carefully place the foot than when peripherally loaded devices (shoes) are present. Further research suggests that the active engagement of the neural elements of the foot may be critically important in determining the overall health of the foot.

Chapter 30

Navicular Disease

Sue J. Dyson

PATHOPHYSIOLOGY OF NAVICULAR DISEASE

Navicular disease is a chronic forelimb lameness associated with pain arising from the distal sesamoid or navicular bone. It is well recognized that in association with advanced navicular disease, fibrillation of the dorsal aspect of the deep digital flexor tendon (DDFT), with or without adhesion formation between the tendon and the navicular bone, is a common feature. Recent clinical studies using magnetic resonance imaging (MRI)¹ and post mortem studies^{2,3} have demonstrated that there may also be abnormalities of closely related structures, including the collateral sesamoidean ligaments (CSLs), the distal sesamoidean impar ligament (DSIL), and the navicular bursa. These structures and the navicular bone are called the podotrochlear apparatus. For the purposes of this chapter, this complex of degenerative changes will be referred to as navicular disease. Primary injury of the DDFT is considered to be a separate condition,⁴ which may have a different etiopathogenesis (see Chapter 32).

Although historically considered to be a single disease, given the variety of clinical presentations it is likely that there are a number of different clinical conditions, of different etiologies, that give rise to pain in the podotrochlear apparatus. It is difficult to conceive a single disease that can result in an insidious onset, slowly progressive bilateral forelimb lameness, or an acute onset, relatively severe unilateral forelimb lameness, each with a variety of different radiological manifestations and with some horses never developing radiological changes. It is curious that sometimes clinical signs become apparent in young horses just commencing work, whereas more typically lameness is seen in mature riding horses. It is also seen in horses with vastly different distal limb conformation. It is a common condition in Quarter Horses, which tend to have narrow, upright, boxy feet, small relative to their body size, as well as in European Warmblood horses, many of which have relatively tall narrow feet. It is also common in Thoroughbred horses, which frequently have rather flat feet, with low collapsed heels, often associated with dorsopalmar foot imbalance. Recent evidence suggests there is a heritable tendency toward the development of navicular disease in Dutch and Hanoverian Warmblood horses.⁵⁻⁷

The factors causing pain in the navicular apparatus, and therefore lameness, are poorly understood. Experience with both radiography and MRI suggests that lesions in both the navicular bone and closely related structures are likely to predate the onset of lameness in some horses.⁸ In some horses, a trigger factor apparently promoting pain and lameness has been a period of enforced rest for an unrelated cause.

There are no good epidemiological studies investigating risk factors for the development of navicular disease. Therefore information is largely anecdotal. The frequency of occurrence of navicular disease appears to vary between breeds. Quarter Horses,⁹ Warmblood horses,¹⁰ and Thoroughbred cross horses¹¹ have a relatively high incidence, whereas the occurrence and/or recognition in some breeds, such as the Finnhorse, Arab,¹² and Friesian, is relatively low.

Biomechanical Considerations

From a biomechanical perspective the podotrochlear apparatus comprising the navicular bone, the CSLs, the DSIL, and the navicular bursa, together with the DDFT, and the distal digital annular ligament are integrally related. The navicular bone, which articulates with the middle and distal phalanges, provides a constant angle of insertion and maintains the mechanical advantage of the DDFT, which exerts major compressive forces on the distal third of the bone. Contact studies between the phalanges in isolated limbs have demonstrated that the greatest forces are applied in the propulsion phase of the stride. This occurs during extension of the distal interphalangeal (DIP) joint, with increased pressure of the DDFT on the palmar aspect of the navicular bone, increased contact between the navicular bone and the middle phalanx, and increased tension in the CSLs.^{13,14} Tension in the DDFT and the distal digital annular ligament promotes stability of the DIP joint. Forces may be altered by foot conformation: in a horse with “weak” heels there is greater extension of the DIP joint compared with a horse with “strong” heels, which results in increased pressure concentrated on the distal aspect of the navicular bone.¹⁵

Compressive forces and stress on the navicular bone were compared in clinically sound horses and horses with navicular disease.¹⁶ Although the mean peak force and stress were similar, the force and stress in the horses with navicular disease were approximately double early in the stance phase of the stride. This early peak stress resulted in a much higher loading rate of the navicular bone in the navicular disease group. The difference in loading patterns was associated with an increased force in the DDFT in the early and mid-stance phases, probably because of increased contraction of the deep digital flexor (DDF) muscle. Contraction of the DDF muscle may result in toe-first ground contact, seen in some horses with navicular disease. It is suggested that pain associated with the navicular bone may result in a positive feedback by increasing the force in the DDFT to avoid heel-first landing, and hence paradoxically increasing the compressive force on the navicular bone. This hypothesis is supported by reduction in peak forces on the navicular bone throughout the stance phase in horses with navicular disease after perineural analgesia of the palmar digital nerves.¹⁷

Although low, collapsed heel conformation has anecdotally been associated with navicular disease, a recent study¹⁸ in Irish draught cross-type horses showed no correlation between the peak force exerted on the navicular bone by the DDFT and the conformation of the hoof capsule, contrary to the earlier results.¹⁵ However, a 1-degree decrease in angle of the solar border of the distal phalanx

resulted in a fourfold increase in peak force on the navicular bone.¹⁸ There was no correlation between the angle of the solar border of the distal phalanx and the degree of heel collapse.

The shape of the navicular bone may be determined at birth, and this may influence the biomechanical forces subsequently applied to the bone (Figure 30-1) and hence

influence the risk of development of navicular disease.^{6,19} Finnhorses and Friesian horses tend to have a straight or convex contour of the proximal articular border of the navicular bone and rarely develop navicular disease. There is a much higher incidence of navicular disease in the Dutch Warmblood breed, and horses in which the proximal articular margin is concave or undulating appear to be at highest risk of development of the disease.^{5,6}

Histopathological Studies

Navicular disease has not been reproduced experimentally; therefore all proposed etiologies remain speculative. Earlier theories suggesting a vascular etiology with arteriosclerosis²⁰ or thrombosis, resulting in ischemia within the navicular bone,²¹ have largely been rejected because of failure to identify ischemic bone or thrombosis, failure to reproduce clinical signs or pathological changes by occluding blood supply to the bone, and expanding evidence demonstrating increased bone modeling.²²⁻²⁵ Post mortem studies to date have focused principally on horses with long-term, chronic disease, generally with advanced radiological abnormalities, reflecting the end stage of a disease complex. These studies identified striking similarities between the pathological features of navicular disease and osteoarthritis (Figure 30-2) in both people and horses.^{24,25}

Studies of aging changes in the navicular bone of normal immature and mature horses suggested that there is a degenerative aging process similar to that seen in joints.²⁴ However, a more recent study investigating not only the navicular bone but also the DDFT, CSLs, DSIL, and navicular bursa demonstrated no age-related differences between mature horses with no history of foot-related lameness ranging from 4 to 15 years of age.^{2,3} This suggests that there may be an individual susceptibility to degenerative change. Nonphysiological biomechanical factors may promote this susceptibility to degenerative change.^{16,24,26}

The explanation for pain and lameness in horses with no detectable radiological change has been poorly investigated by post mortem studies. However, recent

Fig. 30-1 • Dorsoproximal-palmarodistal oblique radiographic images of the navicular bone to show differences in shape of the proximal articular margin. **A**, Straight. There is an axial cluster of radiolucent zones along the distal border of the bone. **B**, Concave (black arrows). There are variably shaped lucent zones along the distal border of the bone and a large distal border fragment laterally (white arrows).

Fig. 30-2 • Sagittal sections of the navicular bones of a horse with navicular disease (**A**), an age-matched control (**B**), and an immature control horse (**C**). The subchondral bone has an increased area and porosity in **A** compared with **B** and **C**; the trabecular area is decreased, but the trabeculae are thickened. (From Wright IM, Kidd L, Thorp BH: Gross, histological and histomorphometric features of the navicular bone and related structures in the horse, *Equine Vet J* 30:220, 1998.)

clinical experience with MRI has indicated that many horses with evidence of increased modeling of the navicular bone based on increased radiopharmaceutical uptake (IRU) detected using nuclear scintigraphy do have pathological abnormalities of the navicular bone detectable using MRI, with or without concurrent changes in the DDFT, CSLs, DSIL, and navicular bursa.^{27,28}

Degenerative changes in the fibrocartilage on the palmar aspect of the navicular bone occur principally in the distal half of the bone, especially centered around the sagittal ridge in both sound and lame horses.² In horses with navicular disease there is a greater degree of fibrocartilage damage, which may extend into the subchondral bone. Partial-thickness loss of fibrocartilage in this location was one of the most common lesions significantly associated with navicular disease in one study.²⁵ It is likely to represent some of the earliest pathology of one form of this disease but remains difficult to identify *in vivo*, even with the use of MRI.⁸ Degenerative change of the spongiosa is generally only seen dorsal to extensive fibrocartilage damage. Physiological forces result in adaptive remodeling of the subchondral bone in immature horses, with cortical thickening.²⁴ Nonphysiological forces may result in focal fibrocartilage and/or flexor cortex damage, with adjacent subchondral sclerosis dorsal to it, associated with thickening of trabeculae and focal areas of lysis. There may also be edema, congestion, and fibrosis of the marrow stroma within the medullary bone, which may result in a cystlike lesion.

Concurrently there may be fibrillation of the dorsal surface of the DDFT, which may predispose to adhesion formation between the DDFT and regions of partially or fully eroded fibrocartilage on the palmar aspect of the navicular bone. Whether lesions in the DDFT are primary or secondary to preexisting damage of the fibrocartilage currently remains open to debate. However, recent post mortem evidence suggests that there may be non-age-related degenerative vascular and matrix changes in the dorsal aspect of the DDFT in both lame and clinically normal horses.³ Although it has been suggested that vascular occlusion and matrix changes in the DDFT may be age-related,²⁵ the results of a recent study showed that the severity of these changes was greater in horses with palmar foot pain than in age-matched control horses.³ Minor fibrillation of the dorsal aspect of the DDFT was seen in both lame and control horses, whereas deep sagittal splits were only seen in lame horses. Complete occlusion of blood vessels, replacement of normal tendon architecture by focal fibroplasia, and areas of fibrocartilaginous metaplasia were common in the lame horses. As these changes are predominantly seen in the intratendonous septa, there is a strong possibility that they predispose to the development of sagittal splits in the dorsal surface of the tendon along these septal planes. Sharp edges of splits in the DDFT extending from the dorsal surface may cause ulceration of the fibrocartilage of the navicular bone and thus predispose to lesions extending into the medulla.

There is an association between changes of the flexor aspect and distal and proximal borders of the navicular bone.² Similar types of change occur at the proximal and distal aspects but tend to be more extensive distally. Enlarged synovial invaginations are the result of recruitment and activation of osteoclasts following the course of

the nutrient vessels into the spongiosa. This may be associated with local medullary osteonecrosis and the presence of foci of fibrocartilaginous metaplasia and/or enthesioid new bone close to the interface between the DSIL and the navicular bone.

Aging changes were described in the articular cartilage of the navicular bone and the opposing face of the distal phalanx.²⁹ There was loss of proteoglycan and tidemark advancement, which was thought to reflect excessive shear stress in the zone between the calcified and noncalcified articular cartilage. A greater number of tidemarks were seen in horses with clinical signs of navicular disease than normal horses of similar age. However, a more recent study failed to identify significant age-related changes, and low-grade degenerative changes in the articular cartilage were common in both control horses and those with navicular disease.²

Observations from Nuclear Scintigraphy and MRI

Previous studies using tetracycline labeling of bone²² and scintigraphic studies^{27,30} have indicated that there is evidence of increased bone turnover in association with some forms of navicular disease, even in the absence of radiological abnormalities of the bone. IRU predominantly reflects increased osteoblastic activity³¹ but is not synonymous with either pain or lameness.³² IRU may reflect a functional adaptation to foot conformation and the biomechanical forces on the navicular bone. Comparison between scintigraphy and MRI has demonstrated that many horses with focal moderate or intense IRU have abnormalities of the navicular bone detectable using MRI.²⁷ However, scintigraphy can also produce false-negative results, indicating that pathological abnormalities of the navicular bone are not always associated with increased osteoblastic activity.

A comparison of MRI findings in control horses with no history of foot-related pain and horses with chronic palmar foot pain showed significant alterations of the podotrochlear apparatus in the lame horses.³³ A comparative MRI and post mortem study showed good correlation between the lesions identified using MRI and histopathological findings.³⁴ Clinical experience with MRI in horses with foot pain provides support for the progression of lesions as outlined above and has demonstrated some earlier lesions than those investigated post mortem.⁸

However, a group of horses has also been identified with no detectable abnormalities of the flexor fibrocartilage or cortex but with diffuse abnormalities of the medulla characterized by increased signal intensity in fat-suppressed magnetic resonance (MR) images. Post mortem examination of several such horses revealed evidence of early fat necrosis with a moth-eaten appearance of the trabeculae, with necrosis of bone edges. This may have a different etiopathogenesis.

Hyperintense signal in the medulla of the navicular bone has been ascribed to the presence of edema in the marrow spaces,³⁵ but this was not validated post mortem. Further research is required to determine the true causes of this phenomenon. In our studies, mild or moderate focal or generalized increased signal intensity in fat-suppressed MR images was associated with trabecular thinning and widened intertrabecular spaces.³⁴ High-intensity increased signal associated with irregular decreased signal intensity in T1- and T2-weighted images was associated

with generalized osteonecrosis and fibrosis, with irregular trabeculae, adjacent adipose tissue edema, and prominent capillary infiltration. A recent post mortem study of feet with advanced radiological abnormalities of the navicular bone demonstrated that increased signal intensity in fat-suppressed images correlated with areas of degenerate adipose tissues, hemorrhage or replacement by fibrocollagenous material, or fluid-filled cystic spaces.³⁶

In some other horses, fluid-filled osseous cystlike lesions were seen in the distal aspect of the bone, apparently separate from synovial invaginations, and not associated with any detectable abnormality of the flexor aspect of the bone. Such lesions have not yet been characterized histologically, and their etiology remains speculative, although they may be associated with lesions of the DSIL.

Occasionally horses have been identified with new bone on the palmar aspect of the navicular bone, centered on the sagittal ridge. The cause of this is currently unknown.

Entheses Changes

The presence of entheses new bone on the proximal border of the navicular bone, reflecting previous insertional desmopathy of the CSL, is well documented radiologically^{37,38} and at post mortem examination^{25,37} in both clinically normal horses and horses with navicular disease. Its clinical significance remains uncertain, although more extensive new bone in this location tends to be associated with other signs of navicular disease.^{37,38} Recent experience with MRI has confirmed these findings.¹ Rarely, an avulsion fracture is identified at the insertion of the CSL into the navicular bone.^{8,39} Mineralized and osseous fragments (Figure 30-3) in the DSIL have also been recognized in both normal horses and in horses with navicular disease, and their clinical significance remains difficult to determine. Fragments were unusual in sound horses undergoing

prepurchase radiographic examination,⁴⁰ although their true incidence may be underestimated by radiographic examination compared with MRI or computed tomography (CT). In two post mortem studies, fragments associated with a defect in the distal margin of the navicular bone were more common in horses with navicular disease than in age-matched controls.^{2,25} This has also been my clinical experience.

Fibrocartilaginous metaplasia in the body of the DSIL was more extensive in horses with navicular disease compared with age-matched control horses.² However, no significant differences between groups were seen in the CSLs.

Aging changes have been seen in the region of insertion of the DSIL and DDFT, with a change in fibroblast shape and an increase in proteoglycans.¹⁴ The functional significance of this is not yet known. Evidence of inflammation was recently recognized histologically at the intersection of the DSIL and DDFT in horses with clinical signs of navicular syndrome.^{29,41} Changes reflecting “abnormal stress” at the insertion of the DSIL and DDFT have been demonstrated in horses with poor foot conformation.²⁹ This region is rich in sensory nerve endings, with many arteriovenous complexes that are damaged in horses with navicular disease.⁴²

Clinical experience with MRI has demonstrated that structural abnormalities of the DSIL are often seen in association with abnormal modeling of the distal palmar aspect of the navicular bone, with focal increased signal in fat-suppressed MR images.^{1,28} It has been suggested that this focally increased signal in the distal aspect of the navicular bone at the origin of the DSIL on fat-suppressed images may represent an important early event in the etiopathogenesis of navicular disease.³³ Increased signal intensity may also be seen in the navicular bone close to the insertion of the CSLs in fat-suppressed images.^{1,28} In some horses there is a linear band of increased signal intensity in fat-suppressed images, extending through the middle third of the navicular bone, from the insertion of the CSL to the origin of the DSIL. Abnormalities of the CSL have also been associated with concurrent abnormalities of the navicular bone. Based on clinical experience, it seems that these lesions may be the result of abnormal stresses at the attachments of the CSL and DSIL on the navicular bone, and this may reflect a different mechanism of navicular disease development.⁸

Although endosteal irregularity at the insertion of the DSIL on the distal phalanx may be seen in both horses with and without foot pain,^{33,34} in some lame horses there is evidence of insertional desmopathy, characterized by enthesophyte formation, axial cortical disruption, osseous cystlike lesions, and/or increased signal intensity in the bone at this site in fat-suppressed images, reflecting bone edema or necrosis.⁸

The Navicular Bursa

The incidence and etiology of primary bursitis of the navicular bursa are not known, nor is the relationship to the development of navicular disease. Villous hypertrophy, hyperplasia of synovial lining cells, and venous congestion have been described in association with navicular disease, whereas the synovial membrane appeared uniform in six normal horses of undetermined age.⁴³ However, in another study comparing immature horses, horses with navicular

Fig. 30-3 • Dorsoproximal-palmarodistal oblique radiographic images of two navicular bones showing a large discrete mineralized fragment on the distal medial sloping border of the bone (arrows) (A) and a distal border fragment (white arrows) located distal to the lateral angle of the navicular bone (B); there is a large radiolucent zone in the adjacent navicular bone (black arrow).

disease, and age-matched controls, 3 of 25 age-matched controls had evidence of asymptomatic chronic synovitis. In both the navicular disease group and the age-matched controls, mild hyperplasia and hypertrophy were seen compared with immature horses up to 3 years of age.²⁵ In a more recent study, there was no evidence of acute inflammation within the navicular bursa in horses with palmar foot pain or age-matched control horses²; however, lame horses had marked chronic synovial proliferation compared with control horses.^{2,33} There was a positive association between abnormalities of the bursa and lesions of either the dorsal aspect of the DDFT or the flexor aspect of the navicular bone. Clinical experience with MRI has indicated that abnormal distention of the bursa is a frequent finding in lame horses but is rarely seen in isolation.¹

Associations between Injuries

It is clear from our recent post mortem study, as well as from clinical experience using MRI, that frequently several structures are affected concurrently. It is common to see various combinations of abnormalities of the navicular bone, DDFT, DSIL, CSL, and the collateral ligaments (CLs) of the DIP joint. Clinical MR examination of 263 horses with forelimb foot pain revealed 6 with abnormalities of the navicular bone alone; 29 with concurrent DDFT and navicular bone abnormalities; 60 with various combinations of abnormalities of the navicular bone, DSIL, DDFT, or CSL; 46 horses with CL injury of the DIP joint combined with lesions of the DDFT, CSL, DSIL, or navicular bone; and 25 horses with abnormalities of five or more structures.²⁸ The sequence of injury occurrence remains speculative. It is possible that degenerative changes in several structures may predispose to concurrent injury. The navicular bone, CSL, and DSIL act as a unit and so presumably undergo similar biomechanical stresses. Alternatively, injury to one structure may cause low-grade instability, predisposing to injury of closely related structures.

What Causes Pain?

Pain associated with navicular disease may be caused by venous congestion of the navicular bone. Dilated venules and sinusoids entrapped in fibrous marrow have only been identified in horses with navicular disease.²⁴ Increased intraosseous pressure has been measured in horses with navicular disease.^{44,45} Distention of the navicular bursa may cause pain. The contribution of other causes or sources of pain remains open to speculation, although many sensory nerve endings have also been identified in the CSLs and the DSIL,^{46,47} and given the high frequency of occurrence of concurrent abnormalities in these structures, it is likely that these nerve endings may be important in pain mediation.

The Future

It is clear that degrees of adaptive and reactive change occur in the podotrochlear apparatus and DDFT of all horses. We need to understand better both the factors that stimulate their progression and what causes pain. Identification of genetic and biomechanical risk factors would be useful. Study of horses with early navicular disease should help to establish better the interrelationship between abnormalities of the DDFT, navicular bone, CSL, and DSIL. We need to determine what factors lead to vascular and

matrix changes in the DDFT. Further research into the sensory nerve supply to the podotrochlear apparatus and DDFT may help in understanding what causes pain—and therefore lameness—and how it may be treated.

DIAGNOSTIC CONSIDERATIONS

History

Most horses are presented with a history of an insidious onset of loss of performance, shortening of stride, or intermittent shifting bilateral forelimb lameness that usually is worst on firm ground. The complaint from the owner may be loss of action, stiffness, unwillingness to jump, especially drop fences, and inability to lengthen stride. Less commonly a horse may have acute-onset, moderate to severe, usually unilateral but sometimes bilateral, forelimb lameness. The condition is rare in ponies compared with horses, and although hindlimb lameness associated with navicular disease is unusual, it does occasionally occur in both ponies and horses.^{48,49}

Clinical signs often are first apparent when the horse is approximately 7 to 9 years of age, although the disease can occur in young horses of 3 to 4 years of age, which may have fairly advanced radiological abnormalities. Lameness may first become apparent after a period of enforced rest because of some other unrelated problem or after a change in management. Development of lameness soon after change of ownership, associated with a change in trimming and shoeing, different work patterns, and altered periods of turnout, is not uncommon.

Clinical Signs

Pain when the horse is standing at rest may be a feature of navicular disease; however, this is a variable finding, and some clinically normal horses habitually point one or both front feet. A horse that has resting pain associated with navicular disease may stand pointing one front foot, sometimes alternating between feet. This is also a feature of horses with primary lesions of the DDFT. Alternatively, an affected horse may pack bedding under the heel or have a tendency to sit on a manger to relieve pressure on the palmar aspect of the foot. Navicular disease is recognized in horses with a wide variety of foot shapes: narrow, boxy upright feet of the Quarter Horse and low, collapsed heels typical of many Thoroughbreds. Navicular disease often is seen in association with poor mediolateral or dorsopalmar foot balance. If lameness is consistently worse on one forelimb, the feet may become asymmetrical in shape, with the lamer foot narrower with a taller heel.

The digital vessels sometimes are palpably enlarged, but this is an inconsistent, nonspecific finding. The response to hoof testers applied to the frog region is often negative,^{22,49,50} although other authors⁵¹ have described a positive response as a fairly consistent feature of navicular disease. Pain may be elicited at the toe if the horse has been repeatedly overloading the toe, resulting in subsolar bruising. Differences in clinical signs observed by different clinicians may reflect genuine differences in horse populations in different geographical locations. Distention of the DIP joint capsule is sometimes seen in association with navicular disease but not invariably so. Increased intra-articular pressure (>40 mm Hg) is said to be associated with navicular disease,⁵² although in my experience there is

considerable variability in the degree of DIP joint distention and pressure in both normal and lame horses.

Lameness is sometimes apparent when the horse is moving on a hard surface in straight lines. It may fluctuate in degree within an examination period or between examinations performed on different days. The horse may show a tendency to stumble associated with an altered foot placement. Overt unilateral lameness may be evident, but in some horses there is only marginal shortening of stride and reduced lift to the stride, which may be difficult to detect if the horse was not previously known to the observer. The horse may move better on a soft surface, even in circles. No clinical signs are detectable in some horses when examined moving in hand on a hard surface. Lameness generally is accentuated if the horse moves in circles on a hard surface, especially with the lame limb on the inside of the circle. In some horses, lameness is apparent only under these circumstances. Less commonly lameness is accentuated when the lame limb is on the outside of a circle. Sometimes lameness cannot be detected unless the horse is ridden, when it may move in a slightly stiff, "flat," and restricted fashion. Recognition of this requires previous knowledge of the horse, knowledge of the expected quality of movement of a horse of that type, or respecting the opinion of the rider that the horse has "lost some action." A vast difference may be detected by desensitizing both front feet. This may be easier to appreciate when riding the horse than watching it.

The response to distal limb flexion is extremely variable. Many horses with navicular disease show a transient, mild increase in lameness.^{22,49,50} Resistance to flexion or marked accentuation of lameness after flexion is unlikely to reflect navicular bone pain. Distal limb flexion of one forelimb may result in increased lameness in the contralateral forelimb because of increased loading of the podotrochlear apparatus, but the same response can also be seen in horses with primary injuries of the DDFT. Elevation of the toe of the foot on a wedge or wooden board, with the contralateral limb picked up, resulting in extension of the DIP joint, may increase lameness, but this response is neither consistent nor pathognomonic for navicular disease.

If the horse's foot conformation is poor and the feet are not trimmed and shod optimally, it is worthwhile improving the trimming and shoeing and reassessing the lameness after several weeks. If the lameness has markedly improved, it is unlikely to reflect navicular disease.

Response to Local Analgesic Techniques

Perineural analgesia of the palmar digital nerves, using 1.5 to 2 mL of mepivacaine hydrochloride (2%) per site, performed immediately axial to the cartilages of the foot usually results in improvement in lameness. However, lameness often is not alleviated fully.^{50,53} Occasionally there is no response. Lameness is generally alleviated completely after perineural analgesia of the palmar nerves, performed at the base of the proximal sesamoid bones, unless there is another concurrent source of pain. Horses should always be reevaluated in both straight lines and circles to determine whether lameness becomes apparent or is accentuated on the contralateral limb.

Intraarticular analgesia of the DIP joint using 4 to 6 mL of mepivacaine can alleviate or improve pain associated with the navicular bone within 5 minutes of injection.^{53,54}

A negative response does not preclude navicular pain because approximately 20% of horses have a negative response to intraarticular analgesia of the DIP joint and a positive response to intrathecal analgesia of the navicular bursa⁵³; this has been correlated with both radiological and post mortem abnormalities of the navicular bone. A positive response to intraarticular analgesia of the DIP joint is a nonspecific result (Figures 30-4 and 30-5) because this technique can alleviate solar pain⁵⁵ and pain associated with the palmar processes of the distal phalanx, the DSIL, the DDFT, and the joint itself.^{46,53,54} Misleading positive results are more likely to occur with larger volumes of local anesthetic solution and evaluation of the response more than 10 minutes after injection.⁵⁶

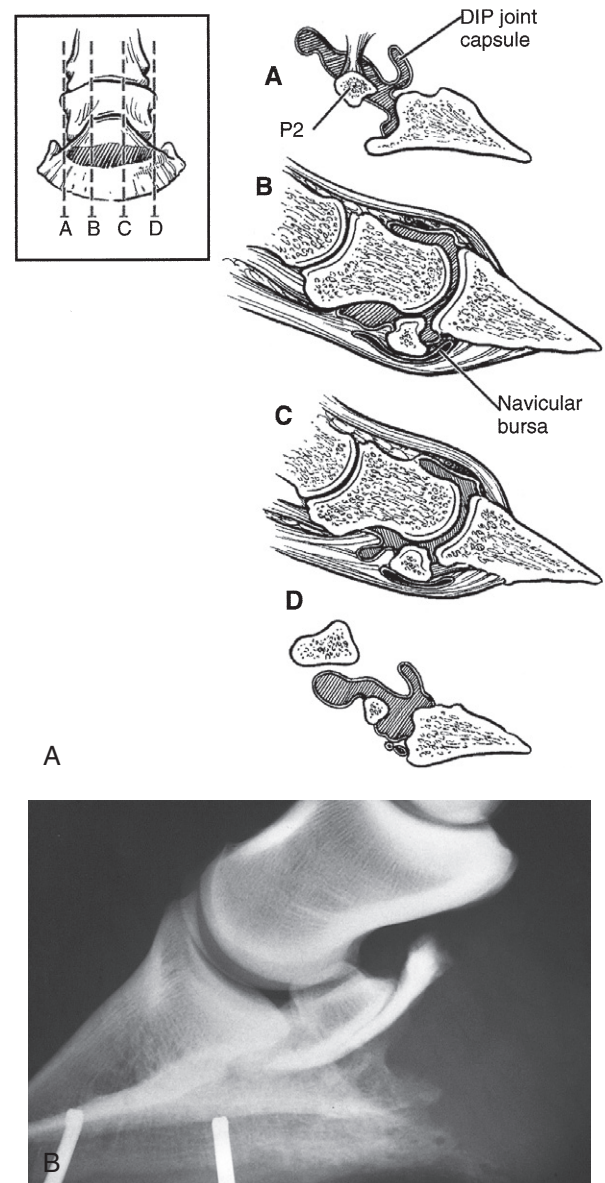

Fig. 30-4 • **A**, Diagram of the relationship between the distal interphalangeal (DIP) joint capsule, the collateral ligaments of the navicular bone, and the distal sesamoidean impar ligament. The four sagittal sections through the foot are denoted with lines A, B, C, and D. **B**, Lateromedial radiographic image of a foot. Three milliliters of radiodense contrast medium has been injected into the navicular bursa to show its proximodistal extent.

Fig. 30-5 • Histological sample stained to show substance P, a small peptide, within thinly myelinated sensory nerves in the collateral ligaments of the navicular bone, appearing to innervate microvessels and pass toward the navicular bone. (Courtesy Dr. R. Bowker.)

A positive response to analgesia of the navicular bursa (3 to 4 mL of mepivacaine) usually reflects primary navicular bone pain, primary bursal pain, or a primary lesion of the DDFT. For accurate injection into the navicular bursa, the needle should be sited in the middle of the flexor surface of the navicular bone. Placement of a needle into the navicular bursa is best performed under radiographic control or should be followed by injection of a radiographic contrast agent to check the accuracy of injection. If the needle is positioned too far proximally, there is danger of injection into the proximal palmar outpouching of the DIP joint or the digital flexor tendon sheath. If the needle is too far distal, it may enter the distal palmar outpouching of the DIP joint. If synovial fluid appears spontaneously in the needle hub, it is unlikely that the needle is positioned correctly. Improvement in lameness is usually seen within 5 minutes of injection of local anesthetic solution. A negative response to analgesia of both the DIP joint and the navicular bursa makes it unlikely that the horse has navicular disease.

Radiographic Examination

Radiographic examination of the navicular bone should be performed after removal of the shoes and appropriate preparation of the feet, and should include lateromedial (LM), dorsoproximal-palmarodistal oblique (DPr-PaDiO), and palmaroproximal-palmarodistal oblique (PaPr-PaDiO) images (Figure 30-6). Flexed oblique images of the DIP joint also are useful for evaluation of its articular margins. Appropriate positioning of the feet is critical for high-quality images. Correct angulation of the x-ray beam for PaPr-PaDiO images is crucial for diagnostic images. Artifacts can be created unless the x-ray beam is tangential to the palmar surface of the navicular bone.^{8,57} The correct angle can vary between 35 and 50 degrees, depending on the shape of the foot.

The proximal border of the navicular bone has two margins: the flexor surface, which is always convex in a DPr-PaDiO image, and the articular margin, which is variable in shape. It can be categorized as concave, undulating, straight, or convex. In the Dutch Warmblood an enhanced risk of the development of navicular disease has been

suggested if the articular margin is concave or undulating rather than convex.⁶

The following features should be evaluated in all images⁵⁷ (Figures 30-6 through 30-9): the presence, number, shape, size, and location of radiolucent zones along the distal borders of the navicular bone; the presence of radiolucent zones along the proximal border of the navicular bone; radiolucent zones within the medulla of the bone; trabecular pattern within the medulla; enthesophyte formation on the proximal or distal aspects of the bone; presence of mineralization within a CSL; presence of articular osteophytes; thickness of the flexor cortex; regularity of outline of the flexor cortex; radiolucent areas in the flexor cortex; new bone formation on the flexor surface; corticomedullary definition; and presence of mineralized fragments distal to the navicular bone.

A grading system for evaluation of the navicular bone in LM and DPr-PaDiO views was devised by Dik.⁵⁸ An adapted version is presented in Box 30-1. The degree of lameness and the degree of radiological abnormality often are poorly correlated. Some horses with navicular bone pain have no detectable radiological change. Some horses, especially young horses, have relatively advanced radiological changes when lameness is first recognized. In many horses with suspected navicular disease the radiological abnormalities are equivocal. The ability to document the progression of radiological change over time (years) is relatively unusual, although the development of a cystlike lesion penetrating the flexor cortex has been noted within 21 days of the onset of acute lameness.⁵⁹

The interpretation of distal border radiolucent zones, which represent synovial invaginations from the DIP joint,^{60,61} has long been subject to controversy. It is generally accepted that the larger the number of radiolucent zones (>7), of variable size and shape, the more likely they are to be of clinical significance. Such radiolucent zones may be seen in association with localized increased radiopacity. Radiolucent zones positioned on the medial and lateral sloping borders of the bone are considered more likely to be of clinical significance. Clusters of axially positioned radiolucent zones, combined with distal elongation of the flexor border of the navicular bone, may reflect abnormal stress at the origin of the DSIL. Comparison between DPr-PaDiO and PaPr-PaDiO views helps to determine the dorsopalmar extent of the radiolucent zones. Proximal border radiolucent zones are occasionally seen and are not normal. They have been seen in association with lesions of the CSL.

Large radiolucent zones close to, but apparently discrete from, the distal border of the navicular bone may occur alone or in association with distal border synovial invaginations. Such radiolucent zones usually extend from the palmar to dorsal cortices when assessed in a PaPr-PaDiO view and are not normally seen in clinically sound horses.

Osseous fragments on the distal border of the navicular bone usually occur at the distal medial and lateral angles of the navicular bone, although less commonly involve the medial or lateral sloping border. Several studies have shown that such fragments occur more commonly in lame horses with other abnormalities of the navicular bone than in clinically normal horses.^{2,25,38,62} Prevalence was low in a group of clinically normal horses undergoing a prepurchase examination.⁴⁰ Such fragments may reflect ectopic

Fig. 30-6 • **A**, Lateromedial radiographic image of a normal navicular bone. **B**, Palmar 45° proximal-palmarodistal oblique radiographic image of a normal navicular bone. **C**, Lateromedial radiographic image of a normal navicular bone; note the smoothly outlined concave depression in the sagittal ridge (*white arrows*) and the concavity in the distal border, a normal fossa (*black arrow*). **D**, Palmar 45° proximal-palmarodistal oblique radiographic image of a normal navicular bone with a well-defined, crescent-shaped radiolucent zone in the central eminence of the flexor cortex. **E**, Palmar 50° proximal-palmarodistal oblique image of a normal navicular bone in a horse with upright foot conformation. The flexor cortex is flatter and thinner compared with **C**.

Fig. 30-7 • **A**, Lateromedial radiographic image of the left front foot of a 6-year-old Warmblood dressage horse with bilateral foot pain. The flexor cortex is abnormally thick. **B**, Sagittal T2*-weighted spoiled gradient-echo MR image of the same foot as in **A**. The dorsal, distal, and palmar cortices are thickened, and there is a small enthesophyte proximally (*arrow*) at the insertion of the collateral sesamoidean ligament.

Fig. 30-8 • A, Dorsoproximal-palmarodistal oblique radiographic image of a navicular bone of a horse with clinical signs of navicular disease. Note the variably shaped and sized radiolucent zones along the distal aspect of the bone. There is proximodistal elongation of the bone. **B**, Dorsoproximal-palmarodistal oblique radiographic image of the navicular bone of a horse with clinical signs of navicular disease. Lateral is to the right. There are multiple variably shaped and sized radiolucent zones along the distal border. The modeling of the proximal medial and lateral margins of the bone is the result of enthesophyte formation.

mineralization in the DSIL, a fracture of the distal border of the navicular bone, or a fracture of an enthesophyte at the origin of the DSIL. The presence of a radiolucent area at the medial or lateral angle of the distal border of the navicular bone suggests the presence of a fragment, which can be present uniaxially or biaxially. Fragments can be seen as an incidental abnormality, especially if the opacity of the adjacent navicular bone is normal, but if seen in association with a radiolucent area, they are more likely to be associated with lameness. Such fragments have been associated with marked reactions in the adjacent navicular bone seen in MR images, presumably the result of chronic movement, or associated with adhesions to the DDFT and/or associated lesions of the DSIL. Fragments are most easily detected in a DPr-PaDiO image, but the ease with which they can be seen is somewhat position dependent. In some horses the presence of a fragment can be verified in a PaPr-PaDiO image, in which an opacity representing the fragment is usually seen superimposed over the spongiosa of the navicular bone. Fragments displaced from the proximal border of the navicular bone are rare and in my experience have been associated with lameness and presumably reflect an avulsion at the insertion of the CSL.³⁹

A crescent-shaped lucent zone in the flexor cortex of the navicular bone in the sagittal ridge (see [Figure 30-6, D](#)) seen in a PaPr-PaDiO image is considered to be a normal variant, representing a reinforcement line.⁶³ The crescent-shaped lucent zone in the sagittal ridge of the navicular bone is rarely seen in very young horses. It represents early

Fig. 30-9 • A, Dorsoproximal-palmarodistal oblique radiographic image of a navicular bone with a radiolucent defect in the flexor cortex of the navicular bone medially (*arrow*). The bone appeared normal in all other radiographic projections. The horse had a bilateral forelimb lameness, which was improved by analgesia of the distal interphalangeal joint or navicular bursa. **B**, Dorsoproximal-palmarodistal oblique radiographic image of a navicular bone with a large cystlike lesion within the spongiosa of the bone, which penetrated the flexor cortex of the bone (see **C**). The horse had a bilateral forelimb lameness that was worse on soft ground with the lamer limb on the outside of a circle. Lameness was improved by palmar (abaxial sesamoid) nerve blocks. **C**, Palmaroproximal-palmarodistal oblique radiographic image of the same navicular bone as in **B**, with a large lucent area penetrating the flexor cortex of the bone. There were extensive adhesions between this defect and the deep digital flexor tendon.

navicular bone modeling in response to stress and is of unknown clinical significance. A relatively sclerotic reinforcement line develops in the subchondral bone parallel with the flexor cortex in the region of the sagittal ridge. The intervening bone is relatively radiolucent and is projected in the PaPr-PaDiO image as the crescent-shaped lucent zone in the sagittal ridge. If the bone between the reinforcement line and the flexor cortex becomes compacted, then the radiolucent zone becomes less clear and may be obliterated. An ill-defined loss of opacity at the most palmar aspect of the sagittal ridge has been seen as an incidental finding, with no other pathological change, but may be a precursor to the development of clinically significant degeneration.

Central or acentric radiolucent zones, cystlike lesions, in the spongiosa of the navicular bone seen in DPr-PaDiO

BOX 30-1

Radiological Findings of the Navicular Bone in Normal and Diseased Horses

Grade	Condition	Radiological Findings
0	Excellent	Good corticomedullary demarcation; fine trabecular pattern. Flexor cortex of uniform thickness and opacity. No radiolucent zones along the distal border of the bone, or several (<6) narrow conical radiolucent zones along the horizontal distal border. Right and left navicular bones symmetrical in shape.
1	Good	As above, but radiolucent zones on the distal border of the navicular bone more variable in shape.
2	Fair	Slightly poor definition between the palmar cortex and the medulla as a result of subcortical increased radiopacity. Crescent-shaped radiolucent zone in the central eminence of the flexor cortex of the bone. Several (<8) radiolucent zones of variable shape along the distal horizontal border of the navicular bone. Mild enthesophyte formation on the proximal border of the navicular bone. Navicular bones asymmetrical in shape. Proximal or distal extension of the flexor border of the navicular bone.
3	Poor	Poor corticomedullary definition resulting from increased medullary radiopacity. Thickening of the dorsal and flexor cortices. Poorly defined radiolucent areas in the flexor cortex of the bone. Many (>7) radiolucent zones along the distal horizontal or sloping borders of the navicular bone. Radiolucent zones along the proximal border of the bone. Large enthesophyte formation on the proximal border of the bone. Discrete mineralization within a collateral sesamoid ligament. Radiopaque fragment on the distal border of the navicular bone.
4	Bad	Large cystlike lesion within the medulla of the navicular bone. Radiolucent region in the flexor cortex of the navicular bone. New bone on the flexor cortex of the navicular bone.

images are almost invariably of clinical significance (see Figure 30-9, B and C). They usually involve the middle third of the bone from proximal to distal, but not invariably so. In some horses such lesions can be seen to involve the flexor cortex of the bone in PaPr-PaDiO images. However, not all such lesions involve the flexor cortex. Moreover, some lesions penetrate the flexor cortex, but this cannot be verified radiologically. This depends on which part of the flexor cortex is tangential to the x-ray beam, the location of the lesion, and its size. A large radiolucent area in the flexor cortex of the navicular bone is invariably of clinical significance, and in some horses is the only detectable radiological abnormality. Such lesions usually occur at the sagittal ridge or abaxial to it. The lesion usually reflects erosion of the overlying fibrocartilage and adhesions of the DDFT. There may be associated increased radiopacity of the trabecular bone dorsal to the lesion.

New bone formation on the flexor border of the navicular bone is usually only detectable in a PaPr-PaDiO image and is usually centered around the sagittal ridge. It has only been seen in association with lameness and has not

necessarily been seen in conjunction with other abnormalities of the navicular bone.

The thickness of the cortices of the navicular bone varies within and between horses. The thickness of the flexor cortex is easiest to evaluate in a well-positioned LM image (see Figure 30-6). Like any bone, shape is influenced by Wolff's law. In a sound horse with one foot that is much more upright than the other, the flexor cortex of the more upright foot is often thinner than the contralateral foot. In one form of navicular disease there is progressive thickening of the cortices of the bone (see Figure 30-7) and the trabeculae of the spongiosa.²⁵ Abnormal thickness of the flexor cortex of the navicular bone probably reflects pathological change.

A normal navicular bone has a regular trabecular architecture in the spongiosa that is clearly defined from the dorsal and palmar cortices in both LM and PaPr-PaDiO images. In one form of navicular disease there is generalized increased radiopacity of the spongiosa, involving particularly the middle third of the bone from laterally to medially. This can also develop as a sequel to acute trauma to the bone. However, a thick overlying frog can create increased radiopacity in this region, and this should be differentiated from genuine increased radiopacity. Alternatively, increased radiopacity may be localized toward the palmar aspect of the bone, affecting the endosteal aspect of the flexor cortex. This can be seen in association with abnormal thickness of the cortices of the bone and may be associated with a defect in the flexor cortex not detectable radiologically.

Demarcation between the spongiosa and the flexor cortex of the navicular bone must be assessed from both LM and PaPr-PaDiO images. However, it must be borne in mind that positioning of the foot during image acquisition may influence the appearance of the navicular bone in the skyline projection, and give a false impression of increased radiopacity of the spongiosa. The two views should be compared carefully.

The shape of the navicular bone should be assessed carefully in a LM image.³⁷ Distal extension of the flexor border of the navicular bone may reflect chronic stress at the origin of the DSIL. Proximal extension of the flexor border of the navicular bone may reflect chronic stress at the insertion of the CSLs.

Enthesophytes at the proximal medial and lateral aspects of the navicular bone are best identified in DPr-PaDiO or dorsopalmar images. Small lateral enthesophytes are a common incidental abnormality and presumably reflect asymmetrical stress at the insertion of the lateral and medial CSLs. However, the presence of a large lateral enthesophyte, or a medial enthesophyte, is more likely to reflect abnormal stress on the podotrochlear apparatus and potentially to be associated with lameness.

The position of the navicular bone in a LM radiograph relative to the middle and distal phalanges is partly influenced by the position of the limb during image acquisition. However, occasionally the bone is abnormally close to the distal phalanx. This has been seen in young horses with lameness recognized soon after the introduction of work and has generally been associated with advanced pathological changes of the navicular bone and the DIP joint. This may reflect a congenital abnormality.

Generally the larger number of radiological changes that are present in all radiographic projections, the more

Fig. 30-10 • Solar scintigraphic bone phase images of the left (**A**) and right (**B**) front feet of a 7-year-old Warmblood with left forelimb lameness. There is focal moderate increased radiopharmaceutical uptake (IRU) in the left front navicular bone, with mild diffuse IRU in the region of insertion of the deep digital flexor tendon on the distal phalanx and mild focal IRU in the medial and lateral palmar processes of the distal phalanx. In the right forelimb there is mild diffuse IRU in the navicular bone, mild focal IRU in the lateral palmar process, and moderate IRU in the medial palmar process of the distal phalanx.

likely it is that the horse has clinical navicular disease. The most clinically significant radiological changes likely to reflect navicular disease include cystlike lesions within the medulla (see [Figure 30-9, A](#)) that are discrete from distal border lucencies, generalized increased radiopacity of the medulla, reduced corticomedullary demarcation, new bone on the flexor surface, and erosions of the flexor cortex of the bone (see [Figure 30-9, B and C](#)).

In some horses, concurrent degenerative changes of the DIP joint are also seen, with modeling* of the proximal dorsal articular margin of the navicular bone, the dorsal and palmar articular margins of the middle phalanx, and the extensor process of the distal phalanx.

In some horses the development of advanced radiological changes precedes the recognition of clinical signs. However, the absence of radiological abnormalities of the navicular bone does not preclude the presence of pain associated with the navicular bone and scintigraphic evidence of increased bone modeling.

Contrast Radiography of the Navicular Bursa

Contrast radiography of the navicular bursa may reveal a number of abnormalities not detectable on plain radiographs, including thinning or erosion of the flexor fibrocartilage of the navicular bone, loss of the radiopaque

contrast layer thought to be caused by adhesion formation between the DDFT and the navicular fibrocartilage, and filling defects on the palmar aspect of the bursa perhaps associated with surface fibrillation of the DDFT.^{49,64} The clinical significance of these findings is currently questionable because it has been well recognized that thinning of the flexor fibrocartilage is a normal aging change, and the clinical significance of surface fibrillation of the DDFT is still open to debate.

Nuclear Scintigraphy

Tetracycline labeling of bone has revealed increased bone turnover in the navicular bone in navicular disease.^{22,23} Nuclear scintigraphy offers a sensitive method of detecting increased bone turnover; however, this is not necessarily synonymous with either pathological change or pain.

Lateral pool (soft tissue) and lateral and palmar (solar) bone phase images of the front feet are required for accurate diagnosis of navicular disease ([Figures 30-10 and 30-11](#)).^{27,28,30,32,65} In solar images of normal horses, uptake of the radiopharmaceutical in the navicular bone and the distal phalanx is approximately similar. However, uneven uptake in various regions of the distal phalanx can complicate interpretation. Care must be taken when interpreting lateral images not to confuse uptake in the cartilages of the foot with uptake in the navicular bone. In solar images, radiopharmaceutical uptake associated with the proximal interphalangeal joint can potentially be superimposed over the navicular bone, unless the foot is well extended during image acquisition and the pastern region is masked with a lead shield. Interpretation can also be difficult because some horses with unilateral lameness have IRU in both the left and right front navicular bones while apparently experiencing pain in only one limb.

*There is confusion between the histological and radiological usage of the terms *remodeling* and *modeling*. Histologically, *remodeling* refers to resorption and formation of bone that is coupled and occurs in basic multicellular units. This regulates the microstructure of bone without altering its shape and is a continuous process, replacing damaged bone with new bone. Thus it cannot be appreciated on radiographs. The term has been used with regard to radiographs to describe the reshaping of bone to match form and function (e.g., after fracture repair), but strictly speaking, the term *modeling* should be used.

Histologically, *modeling* refers to resorption and formation of bone that is not coupled and occurs at anatomically different sites (bone drift). It is a continuous process that regulates the macroscopic appearance of bone according to Wolff's law. In terms of radiography, *modeling* has been used to describe the formation of bone relative to the cartilage model that is being replaced (i.e., the normal formation of bone). Thus the two definitions do not agree; to avoid confusion, strictly speaking the term *modeling* should be applied to describe the change in shape of a bone as it adapts to the stresses applied to it.

Fig. 30-11 • Scintigraphic images of the left front foot of a 5-year-old Warmblood dressage horse with acute-onset left forelimb lameness abolished by palmar digital analgesia and intraarticular analgesia of the distal interphalangeal joint. **A**, Lateral pool phase image. **B**, Solar bone phase image. **C**, Lateral bone phase image. There is focal intense increased radiopharmaceutical uptake in the navicular bone (*arrow*) in all images.

IRU in the navicular bone, with or without IRU at the region of insertion of the DDFT, has correlated well with a positive response to intrathecal analgesia of the navicular bursa³² and with abnormalities of the navicular bone detected using MRI.^{27,28} False-positive results can be found in clinically normal horses, although a relatively high percentage have subsequently developed lameness associated with palmar foot pain.^{32,49}

There is a relatively high incidence of horses with clinical signs compatible with navicular disease and a positive response to intraarticular analgesia of the DIP joint or intrathecal analgesia of the navicular bursa that have no detectable radiological abnormalities of the navicular bone but have IRU in the navicular bone.^{27,28,32} Thus nuclear scintigraphy offers a sensitive method of diagnosis of navicular disease, although if bone necrosis is the principal abnormality or the disease is end stage, radiopharmaceutical uptake may be normal.²⁸

Computed Tomography and Magnetic Resonance Imaging

CT^{66,67} (see Chapter 20) and MRI* (see Chapter 21) are potentially more sensitive than radiography in determining structural lesions of the navicular bone (Figures 30-12 through 30-15) and identifying degenerative changes in the articular cartilage of the DIP joint and primary lesions in the DDFT, the DSIL, and the CSLs. A number of different pathological changes have been identified in the navicular bone that were not detectable with high-quality computed radiography and that may have a different etiopathogenesis. These include:

Fig. 30-12 • Sagittal short tau inversion recovery (STIR) MR image of an 8-year-old dressage horse with loss of forelimb action. There is linear increased signal intensity extending through the navicular bone between the insertion of the collateral sesamoidean ligament and the origin of the distal sesamoidean impar ligament (DSIL) (*white arrows*). There is also increased signal intensity in the DSIL (*arrowhead*).

- Thickening of the flexor cortex with or without endosteal irregularity, sometimes with proximal or distal extension of the flexor cortex, with or without abnormalities of the CSL or DSIL
- Degenerative ulcer-like lesions of the flexor cortex of the navicular bone, often in the distal third, centered

*References 1, 8, 28, 33, 67-71.

around the sagittal ridge, with advanced disease, adhesions of the DDFT, and lesions extending into the spongiosa

- Diffuse increased signal intensity in the spongiosa in fat-suppressed images and reduced signal intensity in T1- and T2-weighted images associated with trabecular and adipose tissue necrosis

Fig. 30-13 • Transverse T2* gradient-echo magnetic resonance (MR) image of the left front foot at the level of the middle phalanx of a 7-year-old pleasure riding horse with some structural abnormalities of the navicular bone seen on MR images. The collateral sesamoidean ligament (arrows) is substantially thickened and is in close apposition to the deep digital flexor tendon (arrowheads), which has a rather irregular dorsal border. Fluid can only be seen in the navicular bursa to the right of the image.

- Axial clusters of synovial invaginations at the distal border of the navicular bone with architectural changes of the DSIL
- A linear band of increased signal intensity in fat-suppressed images between the attachments of the CSL and DSIL, with or without structural abnormalities of the CSL and/or DSIL, reflecting abnormal stress in the podotrochlear apparatus
- Mineralized fragments distal to the navicular bone, with or without osseous reaction in the adjacent navicular bone
- Fluid-filled cystlike lesions in the distal third of the navicular bone

It must also be borne in mind that in a substantial proportion of horses there is a combination of injuries involving not only the navicular bone but also the CSL, DSIL, navicular bursa, and DDFT. In a U.K. study of 347 horses with foot pain that underwent MRI, 12 horses (3.5%) had lesions of the navicular bone alone, 40 horses had lesions of the navicular bone and DDFT (11.5%), and a further 184 (53.0%) had combinations of lesions of the podotrochlear apparatus, navicular bursa, and DDFT.⁷⁰ In a U.S. study of 151 horses in which Quarter Horses predominated, there was a much higher incidence of primary navicular bone lesions.⁷¹ However, horses with more chronic lameness (>6 months' duration) were more likely to have concurrent soft tissue lesions, especially in the CSL.

Endoscopic Evaluation of the Navicular Bursa

Endoscopic examination of the navicular bursa (see Chapter 24) permits evaluation of the fibrocartilage on the flexor surface of the navicular bone, the navicular

Fig. 30-14 • **A**, Sagittal T1-weighted spoiled gradient-echo magnetic resonance (MR) image; **B**, three-dimensional T2* gradient-echo MR image; and **C**, short tau inversion recovery (STIR) MR image of a Grand Prix show jumper with lameness improved by analgesia of the navicular bursa. There were no detectable radiological abnormalities, but there was focal intense increased radiopharmaceutical uptake in the navicular bone. **A**, There are two focal areas of increased signal intensity in the flexor cortex of the navicular bone; the flexor cortex is thickened, and there is marked endosteal irregularity (black arrows). **B**, There is loss of separation between the deep digital flexor tendon (arrows) and the palmar aspect of the navicular bone and close apposition of the tendon and the distal sesamoidean impar ligament (arrowhead). **C**, There is increased signal intensity in the flexor cortex of the navicular bone and in the spongiosa (arrows).

Fig. 30-15 • **A**, Sagittal spoiled gradient-echo magnetic resonance (MR) image; and **B**, sagittal short tau inversion recovery (STIR) MR image of the left front navicular bone of a 8-year-old Warmblood show jumper with recurrent lameness alleviated by palmar digital analgesia. There is diffuse decreased signal intensity throughout the spongiosa of the navicular bone in the T1-weighted image and diffuse hyperintense signal in the STIR image. Radiopharmaceutical uptake was normal. Post mortem examination revealed trabecular and adipose tissue necrosis of the spongiosa of the navicular bone.

bursa itself, the overlying dorsal surface of the DDFT, and a limited view of the distal sesamoidean impar ligament.^{49,72} Thus it is possible to definitively identify adhesions between the DDFT and the palmar aspect of the navicular bone, thinning or full-thickness erosion of the flexor fibrocartilage of the bone, fibrillation of the dorsal aspect of the DDFT, and synovitis of the bursa. Tears in the DSIL have also been identified,⁴⁹ but these are thought to be of traumatic origin rather than part of the navicular disease complex. It is important to differentiate between age-related changes and pathological abnormalities.

OTHER SOFT TISSUE CAUSES OF PALMAR FOOT PAIN

Our understanding of soft tissue pain associated with the palmar aspect of the foot has been limited until recently to identification of pain seen in association with poor foot balance, poor shoeing, or both factors that responded to corrective trimming and shoeing (see Chapter 27). Horses that respond satisfactorily to trimming and shoeing alone are unlikely to have chronic navicular disease, and although navicular bone pain may be present, the precise source of pain cannot be determined. A hemodynamic function for the cartilages of the foot and associated vascular system may contribute to force dissipation (see Chapter 29).⁷³ Peptidergic sensory nerve endings also have been identified in the vascular channels of the cartilages of the foot, close to pacinian-like corpuscles, indicating that this part of the foot may respond to sensory and proprioceptive stimuli. In horses with long toes and underrun heels, the cartilages of

the foot and associated vasculature are less well developed than in a better conformed foot. This may result in less effective force distribution, predisposing to the development of palmar foot pain. In addition, morphological differences have been identified in the digital cushions between “healthy” and “weak” feet, so the digital cushion also may be involved in force dissipation.

With the advent of MRI other soft tissue causes of palmar foot pain were confirmed. These horses usually have no detectable radiological abnormalities. Primary lesions of the DDFT are discussed in detail in Chapter 32. Other injuries that should be considered include the following:

- Desmopathy of the DSIL (see Chapter 33)
- Desmopathy of the CSLs (see Figure 30-13)
- Injury of the distal digital annular ligament
- Navicular bursitis
- Synovitis or osteoarthritis of the DIP joint
- Collateral desmopathy of the DIP joint
- Lesions of the distal phalanx
- Combination injuries

Definitive diagnosis of most of these conditions requires MRI, although ultrasonography performed via the bulbs of the heel or the frog may give some information. Inflammation of the navicular bursa or the DIP joint is rarely seen as single disease entities but accompanies many other causes of foot pain. Injury of the CSL is usually seen in conjunction with other soft tissue injuries or lesions of the navicular bone and rarely alone. Lesions of the DSIL are principally degenerative in nature, although a focal tear in the DSIL has been identified by endoscopic examination of the navicular bursa in an event horse with acute-onset severe lameness that improved after perineural analgesia of

Fig. 30-16 • Gross post mortem specimen of the distal aspect of the navicular bone and the distal sesamoidean impar ligament (DSIL). There is a focal tear in the DSIL (arrow), which had been identified by endoscopic evaluation of the navicular bursa. Surface fibrillation of the deep digital flexor tendon had also been seen.

the palmar digital nerves or intraarticular analgesia of the DIP joint (Figure 30-16).⁷⁴

TREATMENT OF PRIMARY NAVICULAR DISEASE*

Navicular disease is managed because there currently is no cure for this complex condition (Figure 30-17). Rest may not be a useful strategy in the long-term management of many horses with pain in the navicular region because although lameness improves somewhat in most horses after a period of rest, it often returns shortly after the horse resumes exercise. A period of rest for some other cause often precedes the onset of clinical signs of navicular disease. When reviewing literature related to the management of navicular disease it should be borne in mind that much of it relates to palmar foot pain with no definitive diagnosis. The work of Wilson et al¹⁶ suggests that relief of pain is vitally important to alleviate a potentially vicious circle. The horse should be encouraged to land normally, rather than toe first, to avoid increased forces on the navicular bone from the DDFT. However, it must be acknowledged that in some horses with acute lameness in which the principal pathological abnormality is increased signal intensity in fat-suppressed MR images in the spongiosa of the navicular bone, which may reflect bone trauma, the most appropriate treatment may be rest.

In horses with early navicular disease without major radiological abnormalities, medical management using nonsteroidal antiinflammatory drugs (NSAIDs), isoxsuprine, tiludronate, and careful trimming and shoeing may be effective. The aim of medical management is to attempt to return the horse to regular work as soon as possible, starting initially with work predominantly in straight lines. Horses should be exercised as much as possible daily, combining ridden exercise with either turnout or walking on a horse walker. In some horses, use of corrective trimming and shoeing combined with isoxsuprine is sufficient, whereas in others additional analgesia is required using an NSAID. In horses with marked increased radiopacity of the medulla, lesions involving the flexor surface of the navicular bone, or central osseous cystlike lesions, the response to medical management often is unsatisfactory, and surgical treatment may be indicated.

Fig. 30-17 • **A**, Palmar 45° proximal-palmarodistal oblique image of a navicular bone with an irregular contour of the lateral aspect of the flexor cortex. Lateral is to the right. The horse had bilateral forelimb lameness, which was improved by intraarticular analgesia of the distal interphalangeal joint or analgesia of the navicular bursa. **B**, Palmar 35° proximal-palmarodistal oblique image of the same navicular bone as in **A**. The irregularity of the flexor cortex is more obvious. Apparent reduction in corticomedullary demarcation is an artifact, the result of the angle of projection. Lateral is to the right. **C**, The same horse as in **A**. The gross pathological specimen has a defect in the flexor surface, lateral to the sagittal ridge. Lateral is to the right.

MANAGEMENT STRATEGIES

Trimming and Shoeing

Successful management depends on a good relationship with an accomplished, reliable farrier. There is an art and science to farriery, and finding the right combination of the method of trimming and the selection of an appropriate shoe for a given horse often requires some trial and error. Each foot and each horse must be examined individually with regard to the distal limb and foot conformation, limb flight, foot placement, and the intended use of the horse. Both the farrier and the veterinarian must agree, and both must also agree to alter the initial approach if it does not work. Some degree of compromise is always

*The author acknowledges John B. Madison who contributed to this section in the previous edition.

involved. However, some principles apply for all horses with navicular disease. The degree to which lameness can be improved by trimming and shoeing alone depends on the horse's hoof-pastern angle and the previous suitability of trimming and shoeing. If the horse already had a well-conformed foot, little will be achieved.

Care must be taken either to correct or preserve dorso-palmar and lateromedial foot balance whenever possible. This depends to some extent on the natural shape of the horse's foot and its distal limb conformation. Ideally, the hoof-pastern axis should be straight, but whether this can be achieved depends on the horse's conformation. Radical changes in foot trimming may temporarily result in increased lameness; therefore it may be necessary to achieve correct foot balance in stages. The foot should be trimmed to maintain heel mass and shorten the toe to facilitate breakover. Sufficient shortening of the toes usually requires trimming the horn from the solar and dorsal aspects of the foot. The use of the so-called four-point or natural balance trim has recently been favored in some quarters, but the same principles of breakover can probably be achieved with more traditional trimming, provided that the toe is shortened sufficiently (see Chapter 27). Although the four-point trim results in clinical improvement in some horses, in others lameness has been increased, possibly caused by excessive trimming, resulting in altered hoof wall strain,² or by excessive sole pressure.

Elevation of the heel may relieve pressure from the DDFT on the palmar aspect of the navicular bone, with subsequent pain relief. In a short-term study of 12 horses with navicular disease, elevation of the heel using a 3-degree wedge-heel aluminum shoe resulted in significant gait improvement as assessed by force plate analysis.⁷⁵ In a study of normal Dutch Warmblood horses, elevation of the heel using a 6-degree wedge reduced the maximal force on the navicular bone by 24% compared with flat shoes.³ However, not all horses with palmar foot pain need to have the heel elevated, and in many the response is only temporary. A hoof angle between 50 and 55 degrees is considered ideal. Achieving a straight foot-pastern axis is also a goal, but poor foot conformation may prohibit this. Many horses with a low, collapsed heel have a natural angle of no more than 35 degrees, and it is impractical to achieve an angle of 50 to 55 degrees. Lateromedial radiographic images may be helpful to demonstrate to a less-skilled farrier whether a horse needs more or less heel. If the horse's lameness is worsened after elevating the toe using the wedge test, some degree of heel elevation may be beneficial. Elevation of the heel can be achieved by using a wedge heel shoe or a rim or complete wedge pad.

A variety of shoes have been used successfully in the management of horses with navicular disease, including egg bar, egg bar-heart bar, straight bar shoes, and the so-called Tennessee shoe, which moves the point of breakover to just in front of the apex of the frog by placing rails on the palmar aspect of the branches of the shoe. Success has also been achieved in some horses using the natural balance shoe.⁷⁶

The strategy of using shoes that move the weight-bearing axis in a palmar direction in horses with a low, collapsed, and underrun heel is reasonably successful. However, a recent study has shown that using egg bar shoes in clinically normal Dutch Warmblood horses with

well-conformed feet did not reduce force on the navicular bone compared with flat shoes.⁷⁷ The forelimb gait was also described as less animated with egg bar shoes compared with flat shoes. However, these findings cannot necessarily be translated to lame horses with less than ideal foot conformation. Many top-level show jumpers and dressage horses have been shod with egg bar shoes with no apparent detriment to the quality of the gaits. Egg bar shoes provide a greater surface area through which forces are transmitted and clinically seem to help reduce pain associated with either navicular bone pain or the DIP joint. Of 55 horses with clinically diagnosed navicular disease, 53% had permanent relief of lameness after application of egg bar shoes in a follow-up period of 12 to 40 months.⁷⁸ In some horses, clinical improvement took many weeks. Resolution of lameness was seen despite the persistence of a low, collapsed heel. In another study, treated horses showed histomorphometric evidence of altered navicular bone modeling compared with untreated controls.⁷⁹ The shoes should be made-to-measure and of sufficient size and length to provide adequate support to the heel region (Figure 30-18).

Fitting an egg bar shoe is not necessarily easy and depends on the shape of the horse's foot. If the quarters are very wide it can be difficult to "pick up" the heel bulbs. In such horses a traditional open shoe fitted long and wide at the heel or a straight bar shoe may be more appropriate. A correctly fitted egg bar shoe should project beyond the ground-bearing surface of the foot. It is more likely to be pulled off than a standard shoe, and the use of over-reach boots should always be considered, at least when the horse is worked or turned out. These shoes are not suitable for a horse that is going to work in deep mud because they are readily sucked off. In summary, the following principles may aid in the selection of a shoe: correction and then maintenance of dorsopalmar and lateromedial balance, ease of breakover achieved by rolling the toe of the shoe, maintenance of foot (and especially heel) mass, and protection of the palmar aspect of the foot from concussion.

Screw-in studs are used in many competition horses to enhance traction. Some riders just use studs in the lateral branch of the shoe to avoid the risks of tread injuries created by a medial stud in the contralateral limb. This inevitably creates mediolateral imbalance, and therefore care should be taken either to use studs in both branches or to avoid the use of studs. The studs should be positioned as far palmarly as possible to avoid shortening the effective length of the shoe. When the ground is hard, small, pointed studs are preferable to large, square-shaped studs.

Nonsteroidal Antiinflammatory Medication

A wide variety of NSAIDs are used in horses. In general, these drugs should be administered at the lowest dose necessary to achieve the desired effect. There are anecdotal reports that certain NSAIDs are better for horses with foot pain (e.g., meclofenamic acid [Arquel, Pfizer, New York, New York, United States]), but there are no controlled studies to support these claims. Phenylbutazone is widely used, and many, but not all, horses with navicular pain respond to this drug. To determine the lowest effective dose of phenylbutazone, the horse is given a dose of 4 mg/kg

Fig. 30-18 • Lateral (A), palmar (B), and solar (C) photographs of a correctly fitted egg bar shoe. The shoe projects beyond the ground-bearing surface of the foot to cover the bulbs of the heel.

twice daily for 3 days, and the dose is then gradually decreased until the lameness returns. Depending on lameness severity, NSAID treatment may only be necessary when the horse is being used. It should be borne in mind that it has been demonstrated that phenylbutazone may influence bone turnover.⁸⁰ After bone biopsy of the tibia, mineral apposition rate was significantly decreased in horses treated with phenylbutazone (4.4 mg/kg twice daily) compared with untreated, control horses. The clinical significance of this finding in the management of navicular disease is unknown. For horses that are intolerant of phenylbutazone, carprofen ([Rimadyl; Pfizer] 1.0 to 1.5 mg/kg once daily) may be a useful alternative. A short-term study using etodolac, a COX-2 inhibitor, demonstrated significant gait improvement based on force plate data in horses with chronic navicular disease (23 mg/kg orally, once

daily)⁸¹; however, the horses were not in work, and its effectiveness in a clinical setting is unknown.

Isoxsuprine

Isoxsuprine is a β -agonist that causes peripheral vasodilation in people. Its mode of action in the treatment of navicular disease is unknown. It has been suggested that there are no measurable cardiovascular effects of isoxsuprine given orally in the horse.^{78,79} However, orally administered slow-release isoxsuprine resin was absorbed and resulted in thermographic evidence of increased skin temperature of the distal aspect of the forelimbs for about 8 hours after administration.⁸⁰ Isoxsuprine also binds strongly to α -adrenoreceptors⁸¹ and therefore may be active despite insignificant measurable levels in plasma.⁸⁰ The drug also may have some antiinflammatory or hemorrheological

properties that could explain why some horses with navicular disease appear to respond to isoxsuprine therapy. A double-blind clinical trial evaluating the response to isoxsuprine in the treatment of navicular disease demonstrated a decrease in lameness in the treated horses.⁸²

If the horse responds to a trial dose of 0.6 mg/kg twice a day for 30 days, then continued treatment at the same dose given once or twice a day indefinitely may be indicated. Some horses have been treated for 12 weeks and responded satisfactorily and have then shown remission of clinical signs for up to 9 months without treatment. If no response is seen within 30 days, it is unlikely that further treatment will be beneficial. However, some horses that had no response to a dose of 0.6 mg/kg twice daily responded satisfactorily to 0.9 mg/kg twice daily. If lameness is moderate to severe, then treatment should be combined with an NSAID for the first 3 to 4 weeks of treatment. The response to treatment in horses with major radiological abnormalities is generally very poor.

Intraarticular and Intrathecal Medication

It has been demonstrated that potentially therapeutic concentrations of methylprednisolone acetate or triamcinolone acetonide can be achieved in the navicular bursa after injection of the DIP joint.⁸³ However, although lameness associated with navicular disease may be improved by intraarticular analgesia of the DIP joint, the intraarticular administration of hyaluronan with or without corticosteroids (e.g., triamcinolone acetonide, 10 mg) does not usually result in a similar degree of improvement, unless there is concurrent synovitis of the DIP joint. In a study of 128 horses in which lameness was improved by intraarticular analgesia of the DIP joint, the presence of radiological abnormalities of the navicular bone (mild to moderate in degree) resulted in an 18 times lesser likelihood of a successful response to intraarticular medication of the DIP joint with either polysulfated glycosaminoglycan (PSGAG) or methylprednisolone acetate compared with horses without radiological abnormalities.⁸⁸ Intrathecal injection of corticosteroids into the navicular bursa is often more effective clinically and may provide transient relief of clinical signs for up to 2 to 5 months.⁸⁹⁻⁹² In my experience, this treatment is effective only in horses with low-grade radiological abnormalities but can result in very substantial, although temporary, improvement. Repeated treatment may result in the development of dystrophic mineralization. However, the response in horses with radiological⁹¹ or MRI evidence^{91,92} of ulcers (erosions) on the palmar aspect of the navicular bone has been poor.

Other Drugs

Warfarin previously was used to treat horses with "navicular disease," and in one series an 80% success rate was claimed.⁹³ However, these were predominantly pleasure horses and low-level competition horses. Experience in higher-level competition horses produced disappointing results.⁴⁹ Warfarin therapy requires careful adjustment of the dose guided by monitoring of prothrombin time at least at monthly intervals. This, combined with the drug's limited efficacy, has largely resulted in the abandonment of this treatment.

Pentoxifylline and propentofylline are hemorrheological drugs that alter the deformability of the red blood cell

membrane and inhibit platelet aggregation.^{83,94} These drugs are advocated by some clinicians for the treatment of navicular disease, although clinical efficacy to date is largely unknown. No measurable effect on digital and laminar blood flow was seen in healthy horses after oral administration of pentoxifylline.⁸³ A small clinical study using propentofylline resulted in improvement but not alleviation of lameness associated with navicular disease during a 6-week treatment period.⁹⁴ A long-term clinical trial using metrenperone found similar efficacy to isoxsuprine; only 27% of horses had long-term resolution of lameness.⁹⁶

The pathological similarities between navicular disease and osteoarthritis have prompted the use of drugs used for the management of osteoarthritis. Systemic administration of a PSGAG (Adequan, Novartis Animal Health, Basel, Switzerland; 500 mg intramuscularly every 4 days for 7 treatments) resulted in clinical improvement in lameness in treated horses compared with controls during the treatment period.⁹⁶ In my experience, PSGAG treatment has not had any long-lasting benefit on lameness associated with navicular disease.

Tiludronate

Tiludronate is a bisphosphonate that inhibits osteoclastic activity. In a placebo-controlled clinical trial, horses with navicular disease treated by intravenous infusion of tiludronate showed significantly improved lameness scores, but in no horse was lameness completely abolished.⁹⁷ I have treated approximately 20 horses in which increased signal intensity in the spongiosa of the navicular bone in fat-suppressed MR images was the principal abnormality, but the results were disappointing.⁹¹ There is anecdotal suggestion that regional perfusion with tiludronate may be more effective.

Shockwave Therapy

There is anecdotal information that shockwave therapy may temporarily alleviate pain associated with palmar foot pain. In an uncontrolled clinical trial in 42 horses with chronic (>3 months) foot-related lameness, the effect of transcutaneous shockwave therapy or therapy applied between the bulbs of the heel was compared. The latter was more efficacious, although improvement was observed with both treatments.⁹⁸

Chemical "Neurectomy": Cryoneurectomy

Temporary resolution of palmar foot pain can be achieved by chemical ablation of sensory fibers in the palmar digital nerves. Several products are capable of causing a temporary loss of sensation when injected over the nerves. These include Sarapin (a plant alkaloid that is thought to alter transmission in type C fibers; High Chemical Company, Levittown, Pennsylvania, United States), P block, and cobra venom. The product usually is injected over, or directly into, the nerve with a corticosteroid. Injection of absolute alcohol into the perineurium may also be used. Any of these products may result in localized perineural fibrosis, which makes subsequent surgical neurectomy more complicated. Alternatively, the digital nerves may be frozen percutaneously using liquid nitrogen. Both methods result in 2 to 3 months of clinical improvement when successfully applied. In the Editors' experience, these methods work well on

occasion but are unreliable. Return of sensation in most horses is accompanied by a return of the lameness.

Desmotomy of the Collateral Sesamoidean Ligaments

Desmotomy of the CSLs has been described as a treatment for navicular disease.^{99,100} In an initial report from the United Kingdom, 13 of 16 horses treated with this technique were able to work without lameness,⁹⁹ and in a subsequent report, 76% of 118 horses were sound at 6 months, but only 43% remained sound 3 years later.¹⁰¹ Diehl¹⁰⁰ from Germany reported clinical improvement in 50% of 57 horses. In a study from New Zealand, 12 of 17 horses were sound at least 6 months postoperatively.¹⁰² In my experience there is often only short-term (6 to 12 months) improvement in lameness. It was originally suggested that this surgical procedure resulted in alteration of the biomechanical forces on the navicular bone, but clinical improvement may also be the result of sectioning the sensory nerve fibers that run in the CSLs. The original surgical technique described transecting the ligaments near the origin through oblique skin incisions, but the proximal interphalangeal joint capsule can be penetrated by this approach. Better results have been achieved via vertical skin incisions further distally, centered over the CSLs.

Desmotomy of the Accessory Ligament of the Deep Digital Flexor Tendon

Desmotomy of the accessory ligament of the DDFT was described as a treatment for navicular disease in horses with markedly upright foot conformation.¹⁰³ Long-term follow-up results are not available.

Periarterial "Sympathectomy"

Litzke et al¹⁰⁴ described a technique for cutting the sympathetic nerve supply to the lateral and medial digital arteries, either alone or with palmar digital neurectomy. This technique is still practiced in Germany, but the results have not been well documented.

Palmar Digital Neurectomy

If lameness associated with navicular disease is completely eliminated by perineural analgesia of the palmar digital nerves, then palmar digital neurectomy may be considered as a treatment of last resort.¹⁰⁶⁻¹¹⁰ The technique has been associated with a clinically significant number of complications, including failure to alleviate lameness, recurrence of lameness, complete or partial rupture of the DDFT, subluxation or luxation of the DIP joint, neuroma formation, and failure to recognize either subsolar infection or penetrating injuries of the palmar aspect of the foot. Case selection is very important. Horses with preexisting pathology of the DDFT are probably at highest risk of subsequent rupture of the DDFT. If there is radiological evidence of a substantial

defect in the flexor surface of the navicular bone, DDFT lesions are likely, and these horses should not be treated by neurectomy. A variety of techniques of palmar digital neurectomy have been described. Recent work suggests that the simple guillotine technique results in the longest period of desensitization and less neuroma formation compared with epineural capping and carbon dioxide laser division.¹⁰⁷ Surgery should be delayed for at least 7 days after perineural analgesia. For neurectomy, I use two long (3- to 4-cm) incisions just dorsal to the medial and lateral edges of the superficial digital flexor tendon starting just below the base of the proximal sesamoid bone. The nerve is gently stretched and transected using a scalpel blade as far distally and proximally as possible. Approximately 50% of horses have one or more (up to five) accessory branches that must be divided to achieve complete desensitization of the heel region. In most instances the accessory branches are located abaxial to the palmar digital nerve and run in a palmar direction and parallel to the ligament of the ergot. If an accessory branch is located at one surgical site, there are invariably accessory branches associated with the remaining palmar digital nerves. The incision is closed in a single layer, and the horse is confined to a box stall with handwalking only for 30 days. Phenylbutazone (2.2 mg/kg twice daily) is administered for 10 days. This limited exercise, combined with minimal handling of the nerve(s) intraoperatively, seems to reduce the risk of neuroma formation.

The horse is shod in the manner that was most successful before surgery. This procedure usually provides relief of clinical symptoms in approximately 65% to 70% of horses for approximately 12 to 18 months postoperatively.^{108,109} Individual horses may have recurrence of lameness sooner.

With careful handling of the nerve intraoperatively, followed by conservative postoperative management, neuroma formation is uncommon. A painful neuroma, which may occur several months after surgery, may be successfully managed with perineural injections of Sarapin and/or triamcinolone acetonide. Occasionally a second neurectomy done proximal to the neuroma is required.

If lameness occurs because of reinnervation, surgery may be repeated, assuming that perineural analgesia of the palmar digital nerves still results in relief of pain. However, reinnervation may be caused by axons sprouting from the proximal nerve stump and anastomosing with other local nerves. Therefore repeated surgery may be less successful.

Decompression of the Navicular Bone by Surgical Drilling

A technique for drilling cystlike lesions in the navicular bone through an endoscopic approach was recently described, but long-term follow-up results are not available.^{111,112} The rationale is to provide decompression to reduce intraosseous pressure.

Chapter 31

Fracture of the Navicular Bone and Congenital Bipartite Navicular Bone

Sue J. Dyson

Fractures of the navicular bone occur in a variety of configurations. The most common is a slightly oblique parasagittal fracture, medial or lateral to the midline. Y-shaped fractures and other comminuted fractures are less common. Avulsion of the entire distal border is rare. Distal border fragments are discussed elsewhere (see Chapter 30). Fractures occur more commonly in forelimbs than hindlimbs. In a series of 40 horses with navicular bone fractures, 28 (70%) occurred in a forelimb.¹ Fractures usually are traumatic in origin, although it is not always possible to identify the cause. Some fractures in hindlimbs have been the result of kicking a wall. Bipartite and tripartite navicular bones have also been described and should be differentiated from a fracture.² These may occur unilaterally, bilaterally or sometimes in 3 or 4 limbs in forelimbs or hindlimbs. It has been suggested that many fractures are pathological secondary to severe navicular disease,³ but this confusion probably arises because lucent zones adjacent to the fracture line and along the distal border of the navicular bone develop rapidly, within months of fracture occurrence.⁴ Palmar (plantar) displacement of fracture fragment(s) may result in laceration of the deep digital flexor tendon (DDFT).⁵ Other fractures of the middle or distal phalanx occasionally occur concurrently.

HISTORY

Lameness associated with a fracture is usually acute in onset and severe. However, sometimes a horse may develop less severe lameness, and radiographic examination reveals evidence of an old fracture, which presumably healed by fibrous union but has recently become unstable. Instability between separate ossification centers can cause unilateral or bilateral mild to moderate lameness or occasionally lameness in three or four limbs.

CLINICAL EXAMINATION AND DIAGNOSIS

A horse with a fracture may be reluctant to bear full weight on the limb. Digital pulse amplitudes may be increased, and in some horses, pain can be elicited by application of hoof testers to the heel or frog regions. Percussion of the frog may be resented. Lameness usually is severe with an acute fracture and may be accentuated as a horse turns. Lameness is usually substantially improved by perineural analgesia of the palmar digital nerves, although it sometimes is unaffected. Diagnosis depends on radiological identification

of the fracture(s). Most fractures are best identified in a dorsoproximal-palmarodistal oblique image (or an “upright pedal” plantarodorsal image in a hindlimb) (Figure 31-1). It is important that frog cleft artifacts not be confused as a fracture. The clinician should examine any radiolucent line carefully to see whether it extends beyond the bone margins or changes position relative to the medial and lateral margins of the bone if the x-ray beam is reoriented 5 degrees medially or laterally. The frog clefts should be well packed with a moldable compound (e.g., Play-Doh, Hasbro, Pawtucket, Rhode Island, United States) and, if necessary, repacked. If doubt persists, a weight-bearing dorsopalmar view and a palmarproximal-palmarodistal oblique image of the navicular bone should determine whether a fracture is present. The palmarproximal-palmarodistal oblique image is also useful for determining the presence of comminution or displacement. The presence of radiolucent zones along the fracture line indicates that it is not of recent origin but rather is likely to have been present for at least several months (Figure 31-2). With fractures of unusual configurations occasionally radiological findings are equivocal or negative and magnetic resonance imaging (MRI) or computed tomography is required for diagnosis.

A bipartite, or less commonly a tripartite, navicular bone is usually characterized by a wider gap between the ossification centers than an acute fracture. There may or may not be radiolucent zones adjacent to the radiolucent gap between the bone fragments. Occasionally this is an

Fig. 31-1 • Dorsoproximal-palmarodistal oblique radiographic image of a navicular bone. There is an acute parasagittal fracture lateral to the midline. Lateral is to the right.

Fig. 31-2 • Dorsoproximal-palmarodistal oblique radiographic image of a navicular bone with a chronic fracture involving the lateral aspect. There are large radiolucent areas adjacent to the fracture line and modeling of the lateral proximal margin of the navicular bone.

incidental finding unrelated to current lameness. Alternatively, it may be seen in association with foot pain resulting from another related cause, such as a DDFT lesion in the same parasagittal plane. In such horses there is no increase in radiopharmaceutical uptake in the navicular bone, whereas in horses with fractures or bipartite navicular bones contributing directly to pain and lameness there is increased radiopharmaceutical uptake in the navicular bone. Bipartite navicular bones may be present in more than one limb, and if lameness is unilateral, it is recommended that the contralateral limb is also examined radiographically.

Proximal displacement of a hindlimb navicular bone secondary to complete rupture of the distal sesamoidean ligament has been reported in a steeplechaser.⁶ The navicular bone was displaced proximally in a lateromedial radiographic image. The horse was managed conservatively and did return to racing.

TREATMENT

Lameness associated with a simple sagittal fracture usually improves progressively with rest, but the prognosis for complete resolution of lameness or return to full athletic function is guarded. Some horses do become sound enough for light hacking, but lameness may be recurrent.^{3,7} Better results have been described in a limited number of horses by trimming the foot to establish a normal hoof-pastern

axis followed by application of four 3-degree wedge pads and a flat shoe to reduce the weight-bearing function of the navicular bone.⁸ The horse is confined to box rest for 60 days and then starts walking exercise for an additional 2 months. The shoe is refitted every 4 weeks with 3 degrees less elevation at each shoeing. However, healing probably is only by fibrous union. Treatment by palmar digital neurectomy may provide symptomatic relief in some horses, but a substantial proportion develop osteoarthritis of the distal or proximal interphalangeal joints and associated lameness.⁷ Internal fixation using a lag screw technique with a specially designed limb jig and radiographic control offers the best prognosis for simple, oblique sagittal fractures.^{1,9} Twenty-three (68%) of 40 horses resumed work. The prognosis was significantly better for horses with fractures of less than 4 weeks' duration than for those with older fractures. Potential complications include splitting the fragment, inability to reduce the fracture resulting in a step deformity, and poor stabilization of the fracture. Experience with MRI has shown that in association with an acute fracture there may be concurrent lesions of the DDFT, which may influence prognosis. The prognosis for horses with more complicated fractures is guarded.

Palmar digital neurectomy has been used successfully in horses with lameness associated with a bipartite navicular bone; however, it is important to be aware that there may also be a related DDFT injury.

Chapter 32

Primary Lesions of the Deep Digital Flexor Tendon within the Hoof Capsule

Sue J. Dyson

ANATOMY

Within the hoof capsule the deep digital flexor tendon (DDFT) is molded to the palmar (plantar) surface of the navicular bone and separated from it by the navicular bursa. Proximally the DDFT is intimately related to the distal digital annular ligament on its palmar aspect. The distal recess of the navicular bursa separates the DDFT and the distal sesamoidean impar ligament (DSIL). The DDFT has a terminal fanlike expansion containing cartilage that occupies the entire space between the medial and lateral palmar processes of the distal phalanx. It inserts on the facies flexoria and semilunar crest of the distal phalanx. The dorsal portion of the DDFT joins with the DSIL immediately before insertion on the facies flexoria of the distal phalanx. There are parallel fibers of dense connective

tissue, separated by loose connective tissue, within which are many sensory nerves and numerous blood vessels.¹ A prominent line (tidemark) indicates the transition from nonmineralized tendon and ligament to mineralized regions of the DDFT and DSIL before attachment to the distal phalanx.²

Within the digit the DDFT induces axial compression of the articular surfaces of the proximal and distal interphalangeal joints.^{2,3} It has an important role in stabilizing the distal interphalangeal joint. The anatomical arrangement of the collateral ligaments of the navicular bone facilitates compression of the articular surfaces of the navicular bone into those of the middle and distal phalanges.² The DDFT has a dorsal fibrocartilaginous pad that supports pressure of the tuberositas flexoria, the transverse prominence on the proximopalmar aspect of the middle phalanx.³

The relationship of the DDFT to the navicular bone varies with the phase of the stride. During the full weight-bearing stance of the stride the DDFT is only in contact with the distal aspect of the bone, whereas in the propulsion phase the DDFT bends over the distal scutum (the fibrocartilaginous insertion of the straight sesamoidean ligament on the middle phalanx) and comes into full contact with the navicular bone. Tension in the DDFT is maximal, and active muscle contraction and the elasticity in the tendon and in its accessory ligament result in extension of the distal interphalangeal joint.³ At the beginning of the swing phase of the stride the tension in the DDFT contributes passively to induce flexion of the interphalangeal joints. During extension of the distal interphalangeal

joint, which is maximum at the propulsion phase of the stride, pull on the DDFT creates a shear force between the DDFT and the DSIL.²

PATHOPHYSIOLOGY

Primary lesions of the DDFT have only recently been recognized clinically, and only limited information concerning pathophysiology is available. A progressive increase in proteoglycans with age was seen in the distal aspects of the DDFT and DSIL, which may be an adaptation to stress.² It was suggested that horses with low, weak heels may be more susceptible to these changes. Similar but more extensive changes were seen in two horses with navicular disease. Lesions within the DDFT within the foot were identified in fewer than 10% of horses with unknown history in a post mortem study of superficial digital flexor tendon and DDFT lesions in the metacarpal region and digit.⁴

In a post mortem study of 38 horses with suspected navicular disease, one horse had a core lesion of the DDFT with no associated pathological condition of the navicular bone⁵; four additional horses had histological evidence of focal regions of necrosis within the tendon concurrent with other pathological conditions of the navicular bone. Surface fibrillation was a common finding in horses with navicular disease but not in age-matched controls. No lesions of the DDFT were described in the age-matched controls. Pool et al⁶ considered lesions in the DDFT to be secondary to navicular disease. Inflammation at the intersection of the DDFT and DSIL was recognized in the Quarter Horse in association with other signs compatible with navicular disease.⁷ It was considered that these lesions may be involved with the pathogenesis of navicular disease.

A variety of different types of lesions of the DDFT have been identified using magnetic resonance imaging (MRI) and confirmed post mortem.⁸⁻¹¹ These include partial or full-thickness sagittal plane splits, dorsal abrasions, fibrillation, and core lesions. Core lesions within the tendon or on the dorsal surface, full-thickness parasagittal splits can be seen alone and are considered primary lesions of the DDFT, whereas fibrillation and small isolated incomplete parasagittal splits are commonly seen in association with other lesions of the podotrochlear apparatus.¹²⁻¹⁴ Core lesions or full-thickness splits usually occur extending proximally from the proximal aspect of the navicular bursa or distal to the navicular bone. Isolated incomplete parasagittal plane splits, minor dorsal abrasions, and fibrillation are seen most commonly from the proximal level of the navicular bursa distally.

In recent studies comparing MRI and histopathology in groups of horses with chronic foot pain and age-matched control horses, the incidence of DDFT lesions was considerably higher than previously recognized.⁸⁻¹¹ Degenerative changes of the DDFT were seen in both groups but were of greater severity in the lame horses. Thickening of septae, with ghosting and occlusion of blood vessels, and fibrocartilaginous and chondroid metaplasia were characteristic findings, which may predispose to fibrillation and dorsal splits of the tendon. Such changes have also been identified in the proximity of necrotic core lesions. The presence of degenerative changes within the DDFT was not age related. With all types of lesions of the DDFT there was a notable absence of acute inflammatory reaction.

Primary deep digital flexor (DDF) tendonitis may be the result of repetitive overstress or an acute-onset traumatic tear, possibly superimposed on preexisting degenerative change. The identification of severe core lesions in young horses that have done relatively little work suggests that some horses may have an inherent predisposition to injury.

Rupture of the DDFT secondary to previous neurectomy of the palmar digital nerves is considered a separate condition; however, it is likely that a preexisting, unrecognized pathological condition of the DDFT predisposes to rupture (see Chapter 70).

Dystrophic or ectopic mineralization within the DDFT was identified radiologically, at the level of the navicular bone and immediately proximal to it, but its clinical significance has been speculative.¹⁵ Enthesioid new bone at the site of insertion of the DDFT on the facies flexoria and semilunar crest of the distal phalanx was described associated with lameness and unassociated with navicular disease.¹⁶ Nuclear scintigraphic examination of horses with palmar foot pain has revealed horses with linear increased radiopharmaceutical uptake (IRU) in the DDFT in pool phase images or focal regions of IRU in the region of insertion of the DDFT on the distal phalanx,^{17,18} either alone or in association with a region of increased uptake in the navicular bone. This has correlated well with lesions identified using MRI.

HISTORY AND CLINICAL SIGNS

Lameness associated with primary DDF tendonitis within the hoof capsule has been identified most commonly in horses that jump,¹²⁻¹⁴ but it has also been seen in general-purpose riding horses. Lameness usually is unilateral, acute in onset, and moderate to severe in intensity. In horses with severe lameness, the horse may point the affected limb at rest. In mild to moderate injuries, lameness may resolve with rest but recur with work and progressively worsen.

There are generally no clinically significant palpable abnormalities of the limb, unless the lesion extends proximally into the pastern region. There is also no response to pressure applied to the foot with hoof testers. Lameness is often worse on a soft surface, especially on a circle, and in some horses is apparent only under these circumstances. A core lesion in the lateral lobe results in lameness worst with the lame limb on the outside of a circle, whereas a medial lobe lesion usually results in lameness worst with the lame limb on the inside of a circle. The response to distal limb flexion is variable; flexion of the nonlame limb may exacerbate lameness in the lame limb. Extension of the distal interphalangeal joint using the board or wedge test may accentuate the lameness.

LOCAL ANALGESIA

Perineural analgesia of the palmar digital nerves immediately proximal to the cartilages of the foot usually, but not invariably, improves lameness; however, rarely is lameness fully alleviated. Perineural analgesia of the palmar nerves at the level of the base of the proximal sesamoid bones usually abolishes the lameness. Intraarticular analgesia of the distal interphalangeal joint results in rapid improvement in lameness in some horses, but in others lameness

persists unchanged. There has been no correlation between the analgesic response and the proximodistal site of the lesion.¹² Analgesia of the navicular bursa often results in improvement in lameness but rarely alleviates it fully. Intrathecal analgesia of the digital flexor tendon sheath may result in improvement in lameness, but this technique is not specific for DDFT lesions and does not reliably alter lameness associated with lesions confined to the insertion.

DIAGNOSTIC IMAGING

Radiography

In some lateromedial radiographic images of the foot a faint outline of the DDFT can be seen; the clinical significance of this finding is unknown. Occasionally a focus of mineralization is seen within the DDFT, at the level of or proximal to the navicular bone, and usually reflects chronic DDFT injury. In a well-positioned, high-detail lateromedial image, entheses new bone or a radiolucent focus may be identified on the facies flexoria of the distal phalanx. This finding has been seen more commonly in heavier Warmblood breeds¹⁶ than in Thoroughbred and cross-bred horses and has been correlated with increased bone activity identified by nuclear scintigraphy.

Ultrasonography

Diagnostic ultrasonographic imaging of the DDFT within the hoof capsule is not easy because of the horny hoof capsule and the difficulties in orientating the ultrasound transducer perpendicular to the line of the tendon fibers. Thus it is easy to create artifacts. The proximal part of the DDFT may be imaged using a 6.5-MHz transducer positioned between the bulbs of the heel, unless the heel is

very contracted. The region of the DDFT overlying the navicular bone and close to its insertion is potentially seen by a solar approach, placing the transducer (7.5 MHz) on the frog. The frog must be sufficiently soft; this generally is achieved by soaking the foot by bandaging a water-soaked sponge on the foot for several hours. If the horn is exceptionally hard, soaking may have to be continued for several days. The horn must also be pared to provide a relatively flat site for placement of the ultrasound transducer. This is difficult to achieve if the horse has a very narrow foot with a deep frog cleft and sulci. Only the region of the DDFT in the midsagittal plane can be successfully imaged. Orientation is achieved most easily in longitudinal images.

A normal DDFT has linear, parallel echoes, and its margins are well defined.²⁰ An anechoic region representing fluid in the navicular bursa is interposed between the DDFT and the echoic line of the palmar aspect of the navicular bone. Lesions are characterized by enlargement of the tendon and thus loss of its parallel margins. Fiber pattern cannot be assessed, but the presence of mineralization can be detected. Lesions extending into the pastern region may be seen as core lesions, but false-negative results may occur. However, identification of a core lesion in the pastern is generally associated with a lesion that extends further distally.

Nuclear Scintigraphy

Pool and bone phase nuclear scintigraphic lateral and solar images of the foot have been used to identify a region of IRU either at the site of insertion of the DDFT on the facies flexoria of the distal phalanx or further proximally within the DDFT^{12,18} (Figures 32-1 and 32-2). Superimposition of a lateromedial radiographic image and a lateral scintigraphic image helps to accurately locate the site of increased

Fig. 32-1 • A, Lateral pool phase scintigraphic image of the left front foot of a 9-year-old event horse with a history of acute-onset severe lameness after competing. Lameness had persisted despite rest for 3 weeks. Lameness was improved by perineural analgesia of the palmar digital nerves or intraarticular analgesia of the distal interphalangeal joint, but it was not affected by analgesia of the navicular bursa. There is linear increased radiopharmaceutical uptake (*arrow*) in the region of the deep digital flexor tendon (DDFT). **B,** Transverse three-dimensional T2*-weighted gradient-echo magnetic resonance image of the same foot in **A**, at the level of the middle phalanx. Medial is to the left. There is a lesion of the dorsal aspect of the lateral lobe of the DDFT, with granulation tissue (*arrow*) protruding into the distended navicular bursa.

Fig. 32-2 • Solar (palmar) bone phase scintigraphic image of the left front foot of a 7-year-old show jumper with acute-onset, chronic left forelimb lameness that was alleviated by perineural analgesia of the palmar digital nerves. There is a focal region of intensely increased radiopharmaceutical uptake in the distal phalanx at the site of the insertion of the deep digital flexor tendon (DDFT) (arrow). Post mortem examination revealed focal bone necrosis and reactive bone at this site associated with the insertion of the DDFT.

radiopharmaceutical uptake. Although the bone phase solar (palmar) view may be more sensitive for identification of abnormal modeling associated with insertional stress, false-positive results may occur.¹⁷

The results from pool phase lateral images have correlated well with findings using MRI, arthroscopic evaluation of the DDFT through the navicular bursa, and post mortem studies. However, the presence of IRU at the DDFT insertion on the distal phalanx does not necessarily reflect an insertional injury; tendon lesions may be restricted to proximal to the navicular bone.¹⁸

Computed Tomography

Computed tomography (CT) can only be performed with the horse under general anesthesia but has the potential to give information about the size, shape, and internal architecture of the DDFT within the hoof capsule. Therefore it is an accurate method of diagnosis of primary DDFT lesions. Lesions have been identified in one or both of the two lobes of the DDFT and were seen as an enlargement of the DDFT with an increase or decrease in density^{21,22} (Figure 32-3). Thirteen of 78 horses examined using CT had abnormalities of the DDFT within the hoof.²¹ Correlation of an abnormal CT scan result with abnormalities verified at post mortem examination has been described without clinical details.²¹ The use of a contrast agent can facilitate identification of relevant lesions and may be helpful in determining the chronicity of the lesion. CT also provides the opportunity to perform image-guided intervention, such as injection of a core lesion.²²

Magnetic Resonance Imaging

MRI can be performed either with the horse under general anesthesia or in a standing sedated horse, and offers the optimal method of diagnosis of primary DDFT lesions^{12-14,23} (Figures 32-4 and 32-5). Lesions are seen best in sagittal and

Fig. 32-3 • Transverse, contrast-enhanced computed tomographic image at the level of the middle phalanx (MP). Medial is to the left. The lateral lobe of the deep digital flexor tendon is enlarged and has a central focal increase in signal density (arrow).

transverse planes. Most core lesions are visible in T1- and T2-weighted images and fat-suppressed images and are characterized by increased signal intensity extending a variable distance proximodistally, often associated with enlargement of a cross-sectional area of the affected lobe. Fat-suppressed two-dimensional fast spin-echo or three-dimensional gradient-echo sequences also are useful for detection of bone pathology at the insertion. Dorsal core lesions within the navicular bursa are often covered dorsally by granulation-like tissue.

Most primary DDFT lesions have been identified immediately proximal to the navicular bone, extending a variable distance proximally, to as far as the proximal aspect of the proximal phalanx.¹⁴ Such lesions are often not detectable using ultrasonography. A smaller proportion of lesions have been identified at the insertion of the DDFT. Lesions usually are restricted to either the medial or the lateral lobe, but occasionally they occur in both lobes. Core lesions or dorsal fiber disruption, sometimes with herniation of fibers and granulation tissue into the navicular bursa, are most common. Focal, full-thickness, sagittal plane splits have also been seen at the level of the navicular bone in association with abnormal signal intensity in the palmar cortex of the bone. Seventy-five of 347 horses (21.6%) with palmar foot pain of previously undetermined cause had primary DDFT injuries diagnosed using MRI.¹⁹ A further 40 horses had combined lesions of the navicular bone and DDFT.

Correlation of the results of MRI examination of cadaver specimens from horses with clinically suspected DDFT lesions and post mortem examination has been good⁹⁻¹¹ (see Figure 32-5). Collagen necrosis and chondroid metaplasia within the DDFT have been seen in regions of increased signal intensity.⁹⁻¹¹ Care must be taken in the interpretation of sagittal plane images in the region of insertion of the DDFT in T1- and T2-weighted high-field magnetic resonance images because there is increased signal intensity in normal horses. This is related in part to the composition of the tendon but also to the magic angle effect, which results from orientation of fibers at approximately 55 degrees to the static magnetic field (see Figure 32-5).

Fig. 32-4 • **A**, Sagittal short tau inversion recovery magnetic resonance image of a left front foot. There is swelling of the distal aspect of the deep digital flexor tendon (DDFT), which has diffuse increase in signal intensity. **B**, Transverse three-dimensional T2*-weighted, gradient-echo magnetic resonance image of the left front foot of a 9-year-old medium-level dressage horse, with lameness improved by palmar digital analgesia and abolished by perineural analgesia of the palmar (abaxial sesamoid) nerves. There is a core lesion of the DDFT characterized by increased signal intensity (white arrow) and some soft tissue proliferation within the navicular bursa (black arrow).

Fig. 32-5 • Sagittal spoiled gradient-echo magnetic resonance image of the right front foot of an advanced event horse with acute-onset severe lameness that was alleviated by perineural analgesia of the palmar digital nerves and improved by intraarticular analgesia of the distal interphalangeal joint. The deep digital flexor tendon (DDFT) is enlarged and has increased signal intensity proximal to the navicular bone (arrow). This correlated with an extensive core lesion at post mortem examination. Increased signal intensity in the DDFT and distal sesamoidean impar ligament distal to the navicular bone reflects the magic angle effect.

SURGICAL EXPLORATION

Endoscopic examination of the digital flexor tendon sheath and the navicular bursa allows visual evaluation of the surface of the DDFT and assessment of its integrity by

probing (see Chapter 24). Some dorsal core lesions of the DDFT are associated with extensive surface fibrillation of the tendon and inflammation of the synovial lining of the navicular bursa with villous proliferation. However, this technique is invasive and provides only limited information about the internal architecture of the tendon, although it does offer the option of surgical debridement of dorsal lesions.

TREATMENT

Successful treatment of horses with core lesions of the DDFT remains a challenge. Core necrosis can ultimately repair by fibroplasia; however, long-term follow-up studies to date indicate a high rate of recurrent lameness after prolonged periods (6-12 months) of box rest and controlled exercise and corrective trimming and shoeing.^{19,24} Lesions often reduce in size, but usually there is persistent high signal intensity on T1-weighted magnetic resonance images. Twenty-nine per cent of 84 horses returned to full athletic function for a period of more than 6 months and up to 4 years.²⁴ In a separate study 25% of 55 horses returned to full athletic function. Lesion type or proximal-distal location did not appear to influence prognosis.²⁵ Longer-term follow-up evaluation indicates that rest for a minimum of 12 to 18 months may result in an improved outcome.^{26,27} Surgical debridement of dorsal core lesions within the navicular bursa was successful in 54% of 63 horses,^{28,29} but with relatively short follow-up time. This technique is only of use for dorsal lesions, not central core lesions or large splits in the DDFT. Complications have included recurrent lameness associated with adhesion formation within the navicular bursa. CT-guided injections of the DDFT have been performed using a variety of preparations (A cell, platelet-rich plasma, stem cells), but long-term follow-up information is not yet available. Short-term improvement may be seen after medication of the navicular bursa and/or digital flexor tendon sheath with corticosteroids, but repeated injections may predispose to progression of lesions.

Chapter 33

The Distal Phalanx and Distal Interphalangeal Joint

Sue J. Dyson

■ PRIMARY PAIN ASSOCIATED WITH THE DISTAL INTERPHALANGEAL JOINT

FUNCTIONAL ANATOMY

The distal interphalangeal (DIP) joint is a complex structure comprising not only the articulation between the middle and distal phalanges, with supporting collateral ligaments, but also the articulation with the navicular bone. It has a close relationship with the distal sesamoid-equin impar ligament (DSIL) and the collateral sesamoid ligaments. The DSIL consists of bundles of longitudinally orientated collagen fibers, interspersed by synovial invaginations from the DIP joint and penetrating blood vessels.

The DIP joint can move in three planes with flexion and extension movements in the sagittal plane, lateromedial movements in the frontal plane, and rotation and sliding in the transverse plane.^{1,2} During normal load bearing and propulsion on a flat, level surface, DIP joint movement is principally flexion and extension. On an uneven surface and a circle, or if the foot is unbalanced, passive movements result in the distal phalanx sliding and twisting relative to the middle phalanx. Movement is restricted by the collateral ligaments of the DIP joint, the deep digital flexor tendon (DDFT), the distal digital annular ligament, the DSIL, and collateral sesamoid ligaments. The degree of sliding and axial rotation within the DIP joint³ may predispose the horse to DIP joint injury and may explain why lameness associated with the DIP joint frequently is accentuated on a circle.

HISTORY

Lameness associated with the DIP joint may be acute or insidious in onset and unilateral or bilateral. It is more common in forelimbs than in hindlimbs but does occur in both. Lameness in horses with unilateral disease tends to be sudden in onset, but those with bilateral lameness may be evaluated because of poor performance (e.g., shortened stride, unwillingness to jump drop fences, or unwillingness to land with one forelimb leading).

CLINICAL SIGNS

The DIP joint capsule often is distended unilaterally or bilaterally. Distention of the joint capsule also can occur

in clinically sound horses; therefore this finding is not pathognomonic for DIP joint pain. However, chronic distention does reflect synovitis, and treatment may reduce the risk of future problems. It is possible that chronic distention can predispose to low-grade instability of the joint. The dorsal proximal outpouching of the joint capsule can be palpated on the distal dorsal aspect of the pastern. Distention may result in obvious swelling, but it may be difficult to appreciate unless the horse has a fine hair coat. When distention of the joint capsule is present, ballottement of fluid from medial to lateral of the dorsal midline should be possible. The degree of distention may vary according to the recent work history.

Pain may be present on flexion or rotation of the distal limb joints. However, a marked reaction to distal limb flexion more likely reflects metacarpophalangeal joint pain. Mediolateral, dorsopalmar, or both types of foot imbalance are frequent findings and are considered important predisposing factors for the development of DIP joint pain. The degree of lameness varies depending on the nature of the underlying pathological change, recent work history, and whether lameness is unilateral or bilateral. With bilateral DIP joint pain the horse may move just a bit “flat” with a slightly shorter than normal stride. Severe lameness may reflect trauma to one of the supporting soft tissue structures of the joint. Lameness may be accentuated by distal limb flexion or rotation of the distal limb joints, but the response is variable. Lameness often is worse on a circle, especially on a hard surface, with the lamest limb either on the inside or outside of the circle.

DIAGNOSIS

Local Analgesia

Pain associated with the DIP joint often improves after perineural analgesia of the palmar digital nerves and sometimes is alleviated fully. However, in some horses perineural analgesia of the palmar nerves at the level of the base of the proximal sesamoid bones is required to completely eliminate lameness.

Intraarticular analgesia of the DIP joint is not specific for pain that affects the joint itself. The potential exists for relief of pain from the navicular bone, the DSIL and the DDFT and their insertions on the distal phalanx, the palmar processes of the distal phalanx,⁴ and the sole, even at the toe.^{5,6} A standard approach is suggested to aid in interpretation of the response. A maximum volume of 6 mL of local anesthetic solution should be used. After injection through a dorsal midline approach, the horse should stand still until reassessment 5 minutes after injection. The clinician should ascertain whether sensation remains around the coronary band and whether any response to hoof testers has been eliminated to determine the specificity of the block. Lameness caused by primary DIP joint pain usually improves rapidly and substantially after intraarticular analgesia. If the lameness persists, the veterinarian should reassess the horse after an additional 5 minutes. If lameness is still apparent, the DIP joint is not a likely primary source of pain. However, after this time the block still could result in further improvement in lameness as the local anesthetic solution diffuses to adjacent

structures, thereby potentially confounding the response to any other block performed at this stage.^{4,7} Intraarticular analgesia of the DIP joint can substantially improve lameness associated with navicular disease within 5 minutes of injection,^{8,9} although 20% of horses with navicular bone pain had a negative response to intraarticular analgesia of the DIP joint.⁸ Therefore the result of intraarticular analgesia of the DIP joint is best interpreted compared with the response to analgesia of the navicular bursa.^{7,8} Intraarticular analgesia of the DIP joint may not relieve pain associated with a primary injury of one of the collateral ligaments, although improvement may be seen if there is concurrent synovitis or osteoarthritis (OA).

A slight or negative response to intraarticular analgesia of the DIP joint does not eliminate completely a response to treatment of the joint, especially if the joint capsule is distended. For example, medication of the joint with hyaluronan and triamcinolone acetonide (10 mg) sometimes may resolve lameness that was not altered by intraarticular analgesia.

Retrieval of synovial fluid from the DIP joint depends on the synovial fluid pressure and position of the needle. Using a dorsal approach to the joint and a 20-gauge needle, synovial fluid usually appears spontaneously in the needle hub and, if the joint capsule is distended, may flow out under pressure. Relief of this pressure may help to resolve

lameness. However, not all horses with considerable pressure within the DIP joint respond to intraarticular analgesia or medication. The pressure within the DIP joint also increases if the contralateral limb is picked up; therefore if the contralateral limb is picked up to aid restraint of the horse for injection of the DIP joint of the ipsilateral limb, a tendency for backflow through the needle puncture site may occur until the contralateral limb is placed on the ground.

Imaging Techniques

Radiography

Comprehensive radiographic examination of the DIP joint should include weight-bearing dorsopalmar, lateromedial, dorsoproximal-palmarodistal oblique, and flexed dorsolateral-palmaromedial and dorsomedial-palmarolateral oblique images of the interphalangeal joints.¹⁰ Because intraarticular analgesia may influence pain associated with the palmar processes of the distal phalanx and the navicular bone, these structures also should be evaluated carefully.

The shape of the extensor process of the distal phalanx varies considerably among horses on lateromedial images (Figure 33-1), but the shape usually is bilaterally symmetrical.¹⁰ Modeling changes of the extensor process can be present without associated lameness. Care should be taken in interpretation of the bony prominences on the distal

Fig. 33-1 • Lateromedial radiographic images of the extensor process of normal distal phalanges. Note the variability in shape.

Fig. 33-2 • Flexed dorsal 60° lateral-palmaromedial oblique radiographic image of the distal interphalangeal joint. There are modeling changes of the articular margins of both the distal interphalangeal and proximal interphalangeal joints.

medial and lateral aspects of the middle phalanx, which always appear larger in bigger-boned horses. Entheses new bone at the origins of the collateral ligaments can be seen as an incidental finding. The DIP joint should be inspected carefully for recognition of small osteophytes on the distal palmar aspect of the middle phalanx and the dorsoproximal aspect of the navicular bone. Joint space congruity and the shape of the proximal articular surface of the distal phalanx should be assessed carefully. A smoothly outlined depression sometimes is seen in the middle of the proximal articular surface of the distal phalanx in clinically normal horses.

The flexed oblique radiographic images—dorsal 60° lateral-palmaromedial oblique and dorsal 60° medial-palmarolateral oblique—enhance detection of periarticular new bone (Figure 33-2) modeling of the distal aspect of the middle phalanx and entheses new bone at the origin of the collateral ligaments of the DIP joint. Care is needed to differentiate between periarticular osteophytes and entheses new bone at the insertion of the digital extensor tendon. Evaluation of the integrity and thickness of the subchondral bone plate of the middle and distal phalanges is important. Discontinuity of the subchondral bone plate may be the first radiological sign of the development of an osseous cystlike lesion. Increased thickness of the subchondral bone plate may occur with OA.

New bone also may develop on the dorsal aspect of the diaphysis of the middle phalanx. Smoothly outlined new bone usually is subsynovial and clinically insignificant, whereas active-appearing, palisading new bone usually is associated with lameness. Palisading is one of the earliest radiological signs but often is missed. The dorsal cortex of the middle phalanx may develop increased radiopacity (thicker), and early proliferative new bone may be seen.

Small, well-rounded mineralized opacities on the dorsoproximal aspect of the distal phalanx are not uncommon and may be present unassociated with clinical signs. Large mobile pieces are more likely to be associated with lameness.

The distal border of the navicular bone also should be evaluated carefully because the radiolucent zones along the distal border represent synovial invaginations from the DIP joint. An increase in size and number of these lucent zones has been observed with chronic synovitis of the DIP joint.

Ultrasonography

Diagnostic ultrasonography with a 7.5- to 13-MHz transducer and a standoff is invaluable for assessment of the dorsal pouch of the DIP joint, the amount of fluid within the joint, and the presence of synovial proliferation. Assessment of the palmar pouch is much more difficult, and evaluation of the articular cartilage is extremely limited. The structure of the proximal aspect of the collateral ligaments of the DIP joint proximal to the hoof capsule can be assessed,^{11,12} as well as the chondrocompedal, chondrocoronal, and distal digital annular ligaments. Using a trans-cuneal approach, the insertion of the DSIL can be assessed.¹³

Nuclear Scintigraphy

Nuclear scintigraphy has been useful in the identification of horses with DIP joint capsule and subchondral bone trauma. It appears to be rather insensitive to the identification of OA unless the disease is advanced.¹⁴ Increased radiopharmaceutical uptake (IRU) is best detected in lateral images.

Diagnostic Arthroscopy

The dorsal and palmar pouches of the DIP joint may be inspected arthroscopically; however, the view of joint surfaces is limited, and complete assessment of the integrity of the articular cartilage is not possible (see Figure 23-5). Access may be enhanced after joint trauma with resultant instability of the joint. Affected horses usually develop long-term lameness problems. Lavage of the joint may be beneficial therapeutically in some horses with chronic DIP joint pain without joint instability. A limited view of the DSIL can be seen from the navicular bursa.

Magnetic Resonance Imaging

Sagittal, frontal, and transverse magnetic resonance (MR) images of the DIP joint permit excellent evaluation of the articular cartilage and subchondral bone of the joint and the dorsal and palmar pouches of the DIP joint capsule (Figure 33-3). The DSIL, DDFT, collateral sesamoidean ligaments, and the navicular bone and bursa also may be assessed. Magnetic resonance imaging (MRI) is the imaging modality of choice for horses with chronic DIP joint pain that does not respond adequately to medical treatment.

DIFFERENTIAL DIAGNOSIS OF PRIMARY DISTAL INTERPHALANGEAL JOINT PAIN

Synovitis

The most common cause of DIP joint pain is synovitis, which may occur unilaterally or bilaterally. Lameness is mild to moderate in degree, and palpable distention of the

Fig. 33-3 • Dorsal three-dimensional T2* gradient-echo magnetic resonance image of the left hind foot of a riding horse with lameness of 3 months' duration. The lameness was completely resolved by intraarticular analgesia. Radiological examination was negative; scintigraphy revealed focal increased radiopharmaceutical uptake in the proximal aspect of the distal phalanx. A focal lesion is present in the subchondral bone plate of the distal phalanx (arrow).

DIP joint capsule usually is present. Intraarticular analgesia generally resolves the lameness. Treatment should be directed to identification of any predisposing causes. Corrective trimming to restore correct foot balance and appropriate shoeing are essential for successful management. Horses with a collapsed heel usually benefit substantially from properly fitted egg bar shoes (see Figure 30-18). The timing of trimming and shoeing can be crucial: if the feet are allowed to get too long, soreness may return.

In my experience, systemic administration of hyaluronan is generally of limited benefit in the initial treatment of horses with acute or chronic lameness, but it may have a role in longer-term management. Intraarticular medication using hyaluronan, with or without short-acting corticosteroids (e.g., triamcinolone acetonide) or polysulfated glycosaminoglycans (PSGAG), is the most effective treatment method. In horses with acute synovitis with only mild lameness, a single treatment with hyaluronan alone may be sufficient, but if the lameness is more severe or chronic, better results may be achieved with a combination of triamcinolone acetonide and hyaluronan. Improvement usually is evident within 5 days of treatment. If lameness persists, better results may be achieved by two additional injections using hyaluronan alone at weekly intervals. Intraarticular treatment with PSGAG is contraindicated if acute inflammation is present, but in horses with more chronic lameness, good results have been achieved using serial (up to five) weekly treatments.^{15,16} PSGAG used systemically may be useful for longer-term management. Treatment is followed by walking for 7 days and then a progressive resumption of work after the final treatment. In some horses, intraarticular therapy results in long-term resolution of the problem. Others require repeated treatments at intervals as needed.

Care is necessary during injection of the DIP joint to avoid puncturing the large vessels on the distodorsal aspect of the pastern. Puncture tends to cause localized fibrosis, and future injections are more difficult. With excellent

Fig. 33-4 • Sagittal three-dimensional T2* gradient-echo magnetic resonance image of the foot of a Grand Prix show jumper. There is loss of the normal homogeneous signal in the cartilage of the distal interphalangeal joint and irregularities in the subchondral bone in the center of the distal phalanx (arrow). Mild periarticular osteophyte formation was evident on radiographs. Scintigraphic examination was unremarkable.

technique, the DIP joint will tolerate well many injections, and the prognosis for future soundness is good.

Osteoarthritis

Osteoarthritis without Radiological Abnormalities

Scintigraphy may be useful in the diagnosis of early subchondral lesions associated with OA. The definitive diagnosis of OA without radiological abnormalities is possible pre-mortem only by MRI (Figure 33-4). Horses may have signs similar to those of primary synovitis, but the degree of lameness may be more severe, especially if the horse is exerted maximally, and the response to intraarticular medication tends to be shorter and less complete. MRI may show a reduced signal intensity within the articular cartilage of the DIP joint, in addition to irregularity in the cartilage surface, with or without concurrent abnormalities in the subchondral bone. The prognosis for sustained future soundness is guarded.

Osteoarthritis with Radiological Abnormalities

Correlation is lacking between modeling in the region of the extensor process of the distal phalanx and lameness associated with the DIP joint. Enthesophytes at the site of insertion of the common digital extensor tendon should be differentiated from osteophytes. Enthesophytes may not be associated with current lameness, but may reflect chronic instability of the joint. The presence of periarticular osteophytes on the distodorsal and palmar aspects of the middle phalanx and the proximal articular surface of the navicular bone is more likely to be associated with lameness (Figures 33-5 and 33-6). Radiological evidence of OA of the DIP joint can be seen with other causes of lameness, such as navicular disease. Horses with primary OA of

Fig. 33-5 • Lateromedial radiographic image of the distal interphalangeal joint of a 7-year-old pleasure horse. Marked enthesophyte formation is present on the dorsoproximal aspect of the distal phalanx at the insertion of the common digital extensor tendon (arrow). In addition, there is a well-rounded fragment on the dorsal aspect of the distal interphalangeal joint (arrowhead) and modeling of the extensor process of the distal phalanx.

the DIP joint may respond better to serial treatments with PSGAG than treatment with hyaluronan and corticosteroids.^{15,16} However, if concurrent severe synovitis is present, primary treatment with triamcinolone acetonide and hyaluronan, followed by intraarticular PSGAG, may yield the best results. In my experience, better results are achieved in horses that are sound after intraarticular analgesia compared with horses that show partial improvement in lameness. Prognosis usually is inversely related to the severity of the radiological abnormalities.⁷

Traumatic Damage to Articular Cartilage

Sudden onset of unilateral lameness may be related to traumatic damage to the articular cartilage of the DIP joint, with or without other concurrent soft tissue damage. Definitive diagnosis is possible only with MRI. Intraarticular medication may provide temporary relief of clinical signs, but the long-term prognosis is guarded.

Joint Capsule Trauma

Traumatic damage to the joint capsule, with or without subchondral bone trauma, usually results in sudden-onset, severe lameness that persists despite rest. Lameness may be accentuated markedly when the horse turns. In the acute stage, no abnormalities are detected on radiographic examination. However, periarticular new bone may develop after several weeks (Figure 33-7). Nuclear scintigraphic examination may show generalized increased radiopharmaceutical uptake in the region of the DIP joint (Figure 33-8). Arthroscopic evaluation in these horses has been

Fig. 33-6 • **A**, Dorsolateral-palmaromedial oblique radiographic image of a flexed distal interphalangeal joint of an 8-year-old show jumper with bilateral forelimb lameness improved by intraarticular analgesia of the distal interphalangeal joints. There is modeling of the proximal articular margin of the distal phalanx (arrow), radiological evidence of osteoarthritis (compare with Figure 33-2). There is also enthesophyte formation on the dorsomedial aspect of the middle phalanx at the origin of the medial collateral ligament of the distal interphalangeal joint. No radiological abnormalities were seen in lateromedial or dorsopalmar radiographic images. **B**, Lateromedial radiographic image of the left front foot of a riding horse with lameness improved by intraarticular analgesia of the distal interphalangeal joint. An articular osteophyte is seen on the dorsoproximal aspect of the navicular bone (arrow), and there is a fragment on the dorsal aspect of the distal interphalangeal joint (arrowhead).

Fig. 33-7 • Lateromedial radiographic image of the left front foot of a 3-year-old Thoroughbred filly with severe lameness that improved substantially after intraarticular analgesia of the distal interphalangeal joint. Enthesiophyte new bone is seen on the dorsal aspect of the middle phalanx, in addition to the small fragment at the extensor process of the distal phalanx. Nuclear scintigraphic examination had revealed a similar pattern of uptake of the radiopharmaceutical to that seen in [Figure 33-8](#).

unrewarding. The response to intraarticular medication has been poor, and the prognosis for return to athletic function despite prolonged rest is guarded.

Subchondral Bone Trauma

Subchondral bone trauma may be focal or more generalized and usually is associated with unilateral lameness, which responds poorly to intraarticular medication and short periods of rest. No detectable radiological abnormalities may be apparent in the acute stage, although Ross¹⁴ described subtle proliferative changes on the distal aspect of the middle phalanx and the proximal aspect of the distal phalanx and a variable degree of subchondral lucency in the proximal aspect of the distal phalanx. Nuclear scintigraphy may be helpful.¹⁴ Several horses have been examined with acute-onset severe and persistent lameness, which was partially improved by intraarticular analgesia of the DIP joint. MRI has revealed a focal lesion in the proximal subchondral bone plate of the distal phalanx, usually axial and toward the palmar or plantar aspect (see [Figure 33-3](#)). Response to conservative management, with or without intraarticular medication or systemic treatment with tiludronate, has been poor.

Osseous Cystlike Lesions

Osseous cystlike lesions occur most often in the center of the proximal aspect of the distal phalanx, midway dorsal to palmar and axial.^{17,18} They vary in size and the presence of visible communication with the DIP joint. Not all are detectable radiologically; some have been identified only either using MRI or at postmortem examination after a poor response to medical treatment of the DIP joint.¹⁶ Horses with large osseous cystlike lesions may be asymptomatic but be lame at a later date. Lameness usually is unilateral, sudden in onset, and moderate to severe. Occasionally lameness is sporadic, but when present it is severe. Osseous cystlike lesions may occur in young immature horses and mature athletes. Not all osseous cystlike lesions that cause pain have active bone turnover; therefore nuclear scintigraphy may not be helpful in determining

Fig. 33-8 • **A**, Dorsal nuclear scintigraphic image of the front feet of a 6-year-old show jumper with sudden-onset, severe lameness markedly improved by intraarticular analgesia of the distal interphalangeal joint. The left forelimb is on the right. Radiopharmaceutical uptake is increased in the subchondral bone of the distal interphalangeal joint. **B**, Lateral scintigraphic image of the left front foot shows increased uptake of the radiopharmaceutical centered on the distal interphalangeal joint (*arrow*). Slight periarticular new bone formation was evident radiologically. Arthroscopic evaluation revealed synovial proliferation. The horse remained lame.

whether a long-standing osseous cystlike lesion is the current cause of lameness. However, currently or recently developing osseous cystlike lesions usually are associated with marked increased bone activity and may be evident on nuclear scintigraphic scans before radiological evidence is evident. Conservative treatment may result in spontaneous resolution of the lameness, with or without resolution of the cyst, but in some horses lameness persists, with or without enlargement of the cyst. Arthroscopic access to a cyst usually may be limited if it is in the central portion of the distal phalanx. Therefore surgical debridement of a well-defined osseous cystlike lesion usually is performed through the hoof wall. Less commonly small osseous cystlike lesions are seen on the dorsoproximal aspect of the distal phalanx, palmar to the extensor process. Such cysts located more dorsally can be debrided arthroscopically. Prognosis depends in part on the integrity of the overlying articular cartilage, and lameness persists in some horses.^{19,20}

Palisading New Bone on Dorsal Aspect of Middle Phalanx

Pain associated with the DIP joint occasionally is associated with new bone formation on the dorsal aspect of the middle phalanx. The origin of this new bone is unknown. Arthroscopic evaluation of the joint may reveal crumbly bone, which is easily debrided, with resolution of lameness in some horses.²¹

Osseous Fragments on the Dorsal Aspect of the Distal Interphalangeal Joint

Small osseous fragments on the dorsoproximal aspect of the extensor process of the distal phalanx may be seen in clinically normal horses. Some are pointed proximally with a flat base and look like the tip of the extensor process, whereas others are well rounded. These fragments may represent separate centers of ossification or may be a manifestation of osteochondrosis and can be incidental radiological findings. If the fragments are seen in association with DIP joint pain, the clinical significance should be interpreted with care. Arthroscopic removal should be considered only if medical therapy of the joint fails.

Fracture of Extensor Process of Distal Phalanx

Fractures of the extensor process of the distal phalanx are discussed in the next section.

Articular Chip Fracture of the Middle Phalanx

Articular chip fractures of the medial or lateral condyle of the distal aspect of the middle phalanx occasionally cause acute-onset lameness.¹⁶ Such fractures can be detected only by flexed oblique radiographic images of the DIP joint. The prognosis after surgical removal is favorable provided joint stability has not been compromised. Surgical repair with arthroscopic guidance also is possible.

Injury of the Distal Sesamoidean Impar Ligament

Focal tears in the DSIL have been seen occasionally in association with sudden-onset, severe lameness that improves after intraarticular analgesia of the DIP joint. In horses with acute lameness, the synovial fluid may be hemorrhagic. Usually no radiological abnormalities are present. Definitive diagnosis is possible with MRI or arthroscopic evaluation of the navicular bursa.⁴ The prognosis for athletic function is guarded. Rupture of a hindlimb DSIL with proximal displacement of the navicular bone has been described in a French steeplechase horse.²² This horse was managed conservatively and did return to racing but then sustained an identical injury in the contralateral hindlimb.

More commonly, architectural changes of the DSIL reflecting chronic degenerative injury are seen in conjunction with other lesions of the podotrochlear apparatus, the navicular bursa, and sometimes the DDFT.^{23,24} There may be an axial cluster of abnormally shaped and sized radiolucent zones in the distal border of the navicular bone. Distal border fragments of the navicular bone may also be associated with DSIL pathology.²⁵⁻²⁸ Definitive diagnosis requires MRI. In low-field MR images the DSIL is difficult to evaluate because of thick slices and inferior resolution compared with high-field images. The presence of a cystic lesion in the distal third of the navicular bone, a distal border fragment, enthesioid new bone at the insertion on

the distal phalanx, or increased signal intensity at the insertion on the distal phalanx are good indicators of DSIL pathology.²⁶

■ FRACTURES AND FRAGMENTATION OF THE EXTENSOR PROCESS OF THE DISTAL PHALANX

HISTORY

Osteochondral fragments of the extensor process of the distal phalanx are classified as type IV fractures.¹⁻³ Small fragments may be traumatically induced or represent a separate center of ossification or may be a manifestation of osteochondrosis. Medium-sized fragments are considered as traumatically induced or separate centers of ossification² or a variation of the traumatically induced, nonunion fracture osseous bodies often observed in other locations on the distal phalanx in foals.⁴ Very large pieces involving the dorsal quarter to third of the articular surface may be developmental,⁵ although it has been suggested that such a fragment may be a sequela to an osseous cystlike lesion.⁶

These fragments involve predominantly the front feet, and lameness may be present. Small fragments can be seen as incidental radiological abnormalities. The fragments almost always are intraarticular, but they usually are nondisplaced to minimally displaced. Large fragments are most commonly seen in young horses, resulting in sudden-onset lameness soon after work commences. However, lameness may be unilateral despite the presence of fragments bilaterally.

CLINICAL AND IMAGING FINDINGS

Low-grade lameness may be present in horses with small fragments. Lameness alleviated by intraarticular analgesia of the DIP joint was present in 16 of 21 horses with osteochondral fragments.³ Lameness may not develop until the horse is in full work when the presence of the fragment induces synovitis. The fragment is seen readily on a lateromedial radiographic image. Many fragments are removed prophylactically.³

Lameness associated with large fragments may be sudden in onset, although radiological abnormalities often appear chronic when lameness is first recognized. A strong fibrous union may maintain stability of the fragment until trauma causes minor fragment loosening. There is often marked increased radiopacity of the parent bone and extensive enthesophyte formation at the insertion of the common digital extensor tendon on the distal phalanx, reflecting chronic joint instability. In some horses the hoof shape becomes triangular or pyramidal; this clinical appearance has been described as *pyramidal disease* or *buttress foot*.²

TREATMENT AND PROGNOSIS

Removal of small fragments under arthroscopic guidance is a well-accepted treatment with a highly favorable prognosis.³ Lameness resolved in 14 or 16 horses with lameness associated with a small fragment, and 5 of 5 horses remained

sound after the fragment was removed prophylactically.³ Horses can return to work within 2 weeks of fragment removal if surgery is prophylactic and at 10 weeks later if preoperative lameness was present.

Guidelines for treatment of horses with medium-sized fragments are less clear. Full recovery after internal fixation of these fragments was reported for two horses in four reports (six horses).^{1,3-5} At least one horse had an acute fracture.⁷ Fragment removal by dorsal midline arthrotomy has been reported in 14 horses with a successful outcome in 8 (57%).¹ Of the six horses with unfavorable results, preoperative duration of lameness exceeded 2 years in three horses, suggesting more favorable results might be expected if preoperative lameness duration were shorter. Horses usually return to full work by 4 months after surgery. Prognosis for large fragments is guarded.

▣ INJURIES OF THE COLLATERAL LIGAMENTS OF THE DISTAL INTERPHALANGEAL JOINT

Desmitis or desmopathy of the medial and/or lateral collateral ligament of the DIP joint results in a variable degree of unilateral or bilateral lameness in forelimbs or, less commonly, hindlimbs.¹⁻⁶ The injury is believed to be caused by the biomechanical forces of sliding and rotation of the joint (e.g., lateral sliding of the distal phalanx and medial rotation, which causes the medial collateral ligament to undergo great strain), sometimes superimposed on a primary degenerative lesion.^{7,8} Degenerative changes are more prevalent toward the insertion of the ligament than farther proximally and include chondroid metaplasia and a unique fissuring necrosis, with cleft formation at the bone ligament interface. There may be osseous resorption at the insertion on the distal phalanx.⁷ Medial injuries are more common than lateral, probably reflecting biomechanical loading. Severe damage to the body of the ligament results in obvious periligamentous soft tissue swelling

and pain immediately proximal to the coronary band, but with many injuries there are no palpable abnormalities. Detection of joint instability is occasionally possible with severe injury. There is an association between extensive ossification of one or both cartilages of the foot and collateral ligament injury.⁹

In horses with severe lameness the caudal phase of the stride is shortened at the walk; at the walk the stance phase is longer than at the trot, resulting in increased extension of the DIP joint and greater stress on the collateral ligaments. At the trot lameness is generally much worse on a circle compared with straight lines, especially on a firm surface. In some horses lameness is improved by palmar digital nerve blocks, but in others palmar (abaxial sesamoid) nerve blocks are required to abolish the lameness. Intraarticular analgesia of the DIP joint may improve lameness if there is associated synovitis or secondary OA. In some horses desmitis of the body of the medial or lateral collateral ligament can be identified ultrasonographically and is characterized by enlargement in the cross-sectional area of the ligament and a diffuse reduction in echogenicity or a hypoechogenic core lesion, with or without thickening of the periligamentar soft tissues (Figure 33-9). Enthesophyte formation at the origin on the middle phalanx may also be seen ultrasonographically or radiologically (see Figure 33-6, A). However, only a limited length of the ligament can be evaluated using ultrasonography, and there are many false-negative results. Placing a wedge under one side of the foot may enable a greater length of the collateral ligament to be evaluated than if the foot is bearing weight uniformly. In a few horses a well-defined osseous cystlike lesion has been identified in the distal phalanx at the site of insertion of a collateral ligament and rarely an osseous cystlike lesion at the origin in the middle phalanx.

Focal IRU in the distal phalanx in the region of insertion of a collateral ligament is a good indicator of the presence of an injury, although not necessarily involving the insertion.¹⁰ However, in many horses MRI is required for definitive diagnosis. Care should be taken when

Fig. 33-9 • Transverse (A) and longitudinal (B) ultrasonographic images of the lateral collateral ligament of the distal interphalangeal joint of a 10-year-old show jumper with acute-onset, severe lameness, worst on a circle. The ligament is enlarged, and a large proportion of the ligament is anechoic.

interpreting low-field images obtained in a standing horse because the magic angle effect may result in artifactual increased signal intensity in the lateral collateral ligament.^{11,12} Magic angle effect may also influence the appearance of high-field MR images in the most proximal aspect of the collateral ligaments.¹³ Confirmation of genuine injury requires identification of changes in size, shape, and signal intensity in T1- and T2-weighted images, and also in fat-suppressed images in acute injury. There may be enthesioid and/or endosteal reaction at the origin and/or insertion. In some horses there is also evidence of bone trauma of the ipsilateral side of the middle or, more commonly, the distal phalanx characterized by diffuse decreased signal intensity in T1-weighted images and increased signal intensity in fat-suppressed images.^{14,15} Osseous cystlike lesions may develop at the origin, or more commonly the insertion, many of which are not detectable radiologically and are only seen using MRI.

Treatment is box rest for a minimum of 2 months followed by at least 4 months of walking exercise, predominantly in straight lines. Longer convalescence may be preferable.¹⁶ In horses with very severe injuries, consideration should be given to application of a foot cast. OA of the DIP joint is a potential sequel if there is instability of the joint. When the medial collateral ligament is damaged, a shoe with a wide medial branch and narrow lateral branch is recommended. For lateral collateral desmopathy, a shoe with a wide lateral branch with a lateral extension and a narrow medial branch is preferred. Medication of the DIP joint is indicated if there is evidence of synovitis or OA. Shock wave or radial pressure wave therapy is popular, although efficacy is questionable.¹⁶ A nonsignificant improvement in treatment success was seen in horses treated by either shockwave therapy or radial pressure wave therapy compared with horses managed conservatively.¹⁶ Surgical treatment of radiographically evident osseous cystlike lesions has been disappointing.¹⁷ Palmar neurectomy has resulted in resolution of lameness in horses that had failed to respond to conservative management, and to date no untoward side effects have been seen.¹⁶

The prognosis for return to athletic function is guarded to fair for horses with injuries that affect primarily the body of the ligament. Horses with acute injuries probably have a more favorable prognosis than those with chronic injuries.^{6,15,16} Overall 47.8% of 69 horses with primary injuries of one or both collateral ligaments returned to full athletic function; 51% of horses with increased signal intensity in fat-suppressed images returned to full function.¹⁶ In a different study 60% of 20 horses, all with increased signal intensity in fat-suppressed images in the injured ligament, returned to full athletic function.⁶ The presence of osseous abnormalities associated with collateral ligament injury did not influence outcome overall, although there was an association between excellent outcome and the presence of enthesioid new bone at the insertion on the distal phalanx.¹⁶ The coexistence of other injuries within the digit resulted in a much poorer prognosis.¹⁶ The prognosis for horses with joint instability, or radiological abnormalities consistent with OA of the DIP joint, is also more guarded. There are anecdotal reports of treatment by stem cell injection, but no reports of clinical efficacy. Although primary traumatically induced injuries unquestionably occur, there is evidence of degenerative pathological change, especially

toward the insertion of the ligament in horses that have failed to respond to treatment.⁷

▣ OSSEOUS CYSTLIKE LESIONS IN THE DISTAL PHALANX

HISTORY

Osseous cystlike lesions in the distal phalanx usually are unilateral, solitary, and range in location from the extensor process to deep within the weight-bearing surface. Debate continues on whether the lesions have a traumatic or developmental origin. When large bilateral lesions are present in a young horse, a developmental component is strongly suggested.¹⁻³

CLINICAL AND IMAGING FINDINGS

Affected horses often are young but mature, and acute-onset, moderate to severe lameness frequently is present. Less commonly the history includes low-grade, intermittent lameness. Occasionally osseous cystlike lesions are identified as incidental radiological findings. Osseous cystlike lesions sometimes are seen in older horses with pain localized to the foot. Such lesions may be clinically significant. Lameness may be exacerbated by distal limb flexion, but results of hoof tester examination usually are negative. Lesions are seen more commonly in the forelimbs, although the hindlimb was affected in 3 of 15 horses in one report.¹ Effusion of the DIP joint occasionally is present, and large bilateral lesions sometimes are associated with a buttress foot appearance.

Lameness often is unaltered by perineural analgesia of the palmar digital nerves, but it is resolved by palmar (abaxial sesamoid) nerve blocks. Intraarticular analgesia of the DIP joint improves lameness associated with osseous cystlike lesions that communicate with the joint. Small articular lesions may not be detectable radiologically, but large osseous cystlike lesions usually are readily identifiable on dorsoproximal-palmarodistal (upright pedal) images. Lesions involving the extensor process are seen readily on lateromedial images. Smaller osseous cystlike lesions located in a very medial or lateral location within the more weight-bearing aspect of the joint are best identified in weight-bearing dorsopalmar images. Nuclear scintigraphic examination may identify small osseous cystlike lesions that are not identifiable radiologically. Osseous cystlike lesions may be associated with IRU, depending on the stage of lesion development and activity of the surrounding bone. However, an osseous cystlike lesion that is scintigraphically silent still may be a cause of lameness. Some lesions can only be identified using MRI.

TREATMENT AND PROGNOSIS

Reports documenting results after either conservative or surgical treatment are limited. In one study, conservative treatment resulted in clinical improvement in approximately 30% of horses, but the prognosis for full recovery was guarded.¹ One report documented favorable results in a horse with bilateral extensor process fragmentation through what were presumed to be preexisting cystic

lesions in the extensor processes.⁴ Anecdotally, arthroscopic debridement of smaller extensor process lesions can be associated with full return to function.⁵ Many lesions are not accessible by arthroscopy or arthrotomy through a dorsal approach. Debridement of distal phalanx lesions through the hoof wall has been described,⁶ but this approach has not gained universal acceptance. However, good results have been achieved in a limited number of horses.⁷ Arthroscopic debridement of centrally located lesions was successful in 10 of 11 horses (91%) 16 to 33 months of age.⁸ Intraarticular medication can be useful in the ongoing management of selected horses; occasionally conservative treatment results in a horse suitable for a limited amount of riding activity.

▣ OSSEOUS TRAUMA OF THE DISTAL AND MIDDLE PHALANGES

Osseous trauma of the middle or distal phalanges usually results in acute-onset, moderate to severe lameness.^{1,2} There are usually no localizing clinical signs. The response to perineural analgesia depends on the location of injury. Diagnosis usually requires MRI, although there may be IRU at the site of injury. Lesions are characterized by an area of increased signal intensity in the cancellous bone in fat-suppressed images, with a corresponding region of low signal intensity in T1-weighted images and sometimes T2* = weighted images (Figure 33-10). The most common site is the distal dorsal aspect of the middle phalanx.³ However, lesions also occur in the distal phalanx, involving especially the palmar aspect, with or without involvement of the navicular bone. These injuries may occur alone or in association with related soft tissue injuries, such as collateral ligament injury. Extensive ossification of a cartilage of a foot may be a risk factor for osseous trauma of the ipsilateral aspect of the distal phalanx.⁴⁻⁶ Lameness is often very slow to resolve, but in horses with uncomplicated

injuries the prognosis is usually favorable, unless there was associated damage of the subchondral bone plate. There are anecdotal reports of beneficial effects of treatment by intravenous infusion of tiludronate.

▣ KERATOMAS AND NEOPLASTIC AND NONNEOPLASTIC SPACE-OCCUPYING LESIONS IN THE HOOF

Keratomas are classified as aberrant, possibly hyperplastic, keratin masses originating from epidermal horn-producing cells of the coronary band.¹ They also have been defined as benign neoplasms originating from the coronary dermis.² As the abnormal horn tubules grow distally toward the toe, hoof wall deformation may occur with disruption of the white line, which may permit entry of infection. Expansion of the mass results in pressure necrosis of the adjacent distal phalanx. Keratomas occur most often in the dorsal half of the foot.³ A keratoma is the most common space-occupying lesion in the hoof, but other neoplastic conditions occur occasionally and result in similar clinical signs, although they usually can be differentiated radiologically.⁴⁻⁸ Other nonneoplastic space-occupying lesions, such as epidermal inclusion cysts and fibrous dysplasia, have been identified that can be differentiated from a keratoma only by histological examination.⁹

HISTORY

Often mild intermittent forelimb or hindlimb lameness exists, or more severe episodes of lameness associated with recurrent subsolar abscessation may have occurred.^{2,3,10-12} Neoplastic conditions may be associated with more severe lameness. Distortion of the hoof capsule may have been noted.

Fig. 33-10 • Sagittal T2*-weighted spoiled gradient-echo (A) and short tau inversion recovery (STIR) (B) magnetic resonance images of a 6-year-old show jumper with acute-onset left forelimb lameness abolished by palmar digital analgesia. Radiographic and ultrasonographic examinations revealed no detectable abnormality. There is reduced signal intensity in the dorsal distal aspect of the middle phalanx in the T2*-weighted image and increased signal intensity in the STIR image, consistent with bone trauma.

Fig. 33-11 • Slightly oblique dorsoproximal-palmarodistal oblique radiographic image of a foot. A smoothly outlined semicircular defect is present in the lateral aspect of the distal phalanx, typical of a keratoma. Lateral is to the right.

CLINICAL SIGNS AND DIAGNOSIS

The hoof capsule, the white line, or both may be distorted but not invariably. Pressure applied with hoof testers may elicit local pain. A variable degree of lameness is present that is alleviated by desensitization of the foot or unilateral palmar block on the side of the lesion. Radiographic examination may reveal a smoothly demarcated radiolucent defect in the margin of the distal phalanx (Figure 33-11). This characteristic is typical of keratomas or other nonneoplastic space-occupying lesions, whereas neoplastic lesions tend to have more irregular margins and may be associated with new bone formation.⁸ Infectious osteitis of the distal phalanx may have a similar appearance, although if the osteitis is chronic, marginal sclerosis with or without new bone formation may be present. The crena at the toe of the distal phalanx should not be confused with a space-occupying lesion. Lesions are best detected in dorsoproximal-palmarodistal oblique, dorsolateral-palmaromedial oblique, or dorsomedial-palmarolateral oblique radiographic images. A keratoma also may be present in the absence of radiological change with only distortion of the hoof capsule.³ If the clinical significance of such a radiological lesion is in doubt, nuclear scintigraphy may be helpful because such lesions usually are associated with focal IRU. Diagnostic ultrasonography also has been used to identify a keratoma at the coronary band.¹³ Small keratomas that were not detected radiologically have also been identified using MRI, although not all are of clinical significance.¹⁴ Occasionally other space-occupying lesions in the more palmar aspect of the foot are only identified in a palmaroproximal-palmarodistal oblique radiographic image of the palmar processes of the distal phalanx.

TREATMENT

Horses with keratomas and other benign space-occupying lesions respond well to surgical excision and have a good prognosis,* but those with neoplastic lesions have a more guarded prognosis. It is best to excise keratomas and other space-occupying lesions through a hoof wall rather than solar approach, if possible. Partial hoof wall resection for keratoma removal was associated with fewer postoperative

complications and a more rapid return to athletic function compared with complete hoof wall resection.¹⁶

FRACTURES OF THE DISTAL PHALANX

Fractures of the distal phalanx are a relatively common cause of lameness in horses from all disciplines and often are the result of trauma, through a misstep or high-speed impact, or kicking a fixed object.¹⁻¹³ Fractures have been classified into six types,^{1,2} but other configurations also occur. Fractures of the extensor process of the distal phalanx (type IV) are discussed elsewhere (see page 355). Fractures of the solar margin of the distal phalanx (type VI), which may occur in foals or adults, are considered separately from fractures of the body of the bone. The latter may be articular or nonarticular and may comprise sagittal (type III), oblique (extending from the midline to the lateral or medial solar margin) (type II), and comminuted fractures (type V), fracture of a palmar process (type I), and, less commonly, fractures of other configurations.

FRACTURE OF THE SOLAR MARGIN OF THE DISTAL PHALANX

Foals

Fractures of the palmar-most aspect of the palmar process of the distal phalanx occur commonly in foals.^{3,4} These fractures originate at the incisure (which normally separates the proximal and distal palmar process angles), continue dorsally toward the toe for 1 to 3 cm, and then extend to the solar margin. They are believed to be caused by shear forces generated by tension of the DDFT or by compression of the solar cortical surface and tension on the dorsal cortical surface during weight bearing. One hypothesis is that excessive trimming of the heel, thus increasing tension in the DDFT, or excessive trimming of the sole of the frog, thus increasing concussion on the distal phalanx and forces on the palmar processes, may be predisposing factors to these fractures, but this was not substantiated in a clinical study, perhaps because of the high overall incidence of fractures (34%).⁵

Clinical Signs and Diagnosis

Lameness usually is mild and extremely transitory, lasting only 1 to 2 days, and may precede radiological identification of a fracture. No consistent response to pressure applied with hoof testers at the heel is present. Diagnosis is based on radiological identification of a discrete osseous body at the palmar process. Fractures may be identified on lateromedial radiographic images, but dorsal 65° proximal-palmarodistal oblique radiographic images are more sensitive. Not all fractures are detectable radiologically.

Treatment and Prognosis

Even with normal management, lameness is only transitory, and spontaneous healing occurs within 4 to 8 weeks with an excellent long-term prognosis. Any type of shoe should be avoided because shoe application in foals can quickly cause contracted feet.

*References 2, 3, 10-13, 15, 16.

Adult Horses

Fractures of the solar margin of the distal phalanx in adult horses occur from the quarters toward the more dorsal aspect of the distal phalanx; these fractures also are referred to as *cracking off*.^{2,6} These fractures may heal, be resorbed, or persist without signs; therefore radiological identification of solar margin fragmentation is not necessarily synonymous with identification of the source of pain causing lameness. Solar margin fractures occur almost exclusively in forelimbs. A geographical influence on the incidence of solar margin fractures is apparent, which may reflect the footing on which the horses work or other undefined factors. In the Editors' experience, these fractures are rare, whereas a study in California of distal phalanx fractures in 274 horses identified 132 (48%) horses with solar margin fractures. However, these fractures frequently occurred in association with radiological evidence of laminitis or another potential cause of lameness, such as navicular disease.⁶ Solar margin fractures as the sole potential cause of lameness were identified only in 25 horses. Irregularity and reduced opacity at the solar margin, with widening of the vascular channels, may be a predisposing factor.

Clinical Signs and Diagnosis

Horses with solar margin fractures often have a history of foot soreness. With an acute solar margin fracture, there may be increased sensitivity to hoof testers at the toe, provided that the sole is not excessively hard. Lameness is removed by perineural analgesia of the palmar nerves in the proximal pastern region or at the level of the proximal sesamoid bones. Diagnosis depends on radiological identification of the fracture or fractures, which may be single or multiple and may affect a variable extent of the solar margin. Primary solar margin fractures usually are single, whereas those that occur in association with laminitis or radiological evidence of demineralization of the solar margin are more likely to be multiple, comminuted, or both. Fractures are identified readily in an appropriately exposed dorsoproximal-palmarodistal oblique radiographic image, but they are overlooked easily if the radiograph is overexposed. The radiographs should be inspected carefully to detect evidence of any other potential cause of lameness that may influence treatment and prognosis.

Treatment

Horses with lameness associated with a solar margin fracture usually require prolonged rest, especially if radiological evidence of preexisting demineralization of the solar margin is present; healing is assessed by periodic radiographic examination. The use of a broad web shoe with a concave solar margin, with or without pads, is recommended. Limited documented long-term follow-up information is available for horses with primary solar margin fractures, but the prognosis generally is favorable.

FRACTURES OF THE BODY OF THE DISTAL PHALANX

Fractures of the body of the distal phalanx occur more commonly in forelimbs than hindlimbs, but they are not uncommon in either limb.^{1,2,7-13} A fracture of the body of the distal phalanx usually results in acute-onset, severe lameness, but nonarticular fractures of a palmar process of

the distal phalanx can occur without severe lameness.¹³ If the fracture is articular, the DIP capsule may be distended. Pain usually occurs when pressure is applied with hoof testers, but this finding may not be a feature of a nondisplaced fracture of a palmar process, especially if it has been present for more than several days. Articular fractures invariably result in continuous lameness, but a nonarticular fracture of a palmar or plantar process of the distal phalanx may be associated with intermittent lameness, especially in a hindlimb. Clinical signs of an articular fracture usually reflect foot pain, and thus regional analgesia often is not required; however, with nonarticular fractures the clinical signs may be less specific, and perineural analgesia is usually required to determine the source of pain. Some palmar process fractures heal only by fibrous union and not osseous union. The radiological identification of a fracture that has healed by fibrous union, which does not have the appearance of a narrow, clearly defined line, should be interpreted with care. Although such a fracture may be unstable and therefore a potential source of pain, the pain causing lameness may not necessarily be related to the fracture.

Fractures of the distal phalanx are a common racehorse injury in North America. Fractures occur most often in the lateral aspect of the left front foot and the medial aspect of the right front foot in association with the counterclockwise direction of training and racing.¹² Fractures of the distal phalanx in the hindlimb in racehorses occur most commonly in the medial aspect of the foot.¹² In sports horses and general purpose horses, fracture of the medial palmar process of the distal phalanx occurs most commonly.¹³

Diagnosis

Diagnosis is based on radiological identification of a fracture (Figures 33-12 and 33-13). A very recent nondisplaced fracture may be difficult to identify radiologically unless the x-ray beam is completely parallel to the fracture line, and many oblique images may be required. The foot should be cleaned thoroughly before radiographic examination to avoid artifacts. The frog clefts may create confusing lucent lines across the distal phalanx; therefore the foot should be packed with a moldable modeling compound (e.g., Play-Doh, Hasbro, Inc., Pawtucket, Rhode Island, United States).

Fig. 33-12 • Dorsoproximal-plantarodistal oblique radiographic image of a left hind foot. The distal phalanx has a complete, articular, parasagittal fracture.

Fig. 33-13 • Dorsomedial-plantarolateral oblique radiographic image of a left hind foot. There is an incomplete, nondisplaced, nonarticular fracture of the medial plantar process of the distal phalanx (arrow). This was not seen on standard radiographic images.

Many articular fractures are seen readily on dorsoproximal-palmarodistal oblique radiographic images, but fractures of the palmar processes and other less common configurations of fracture may not be apparent. A fracture of a palmar process may be evident on a lateromedial radiographic image, but oblique radiographic images of the palmar process are required in many horses. Most of these fractures can be detected in dorsal 30- to 45° lateral (or medial)-palmarodistal oblique radiographic images with the foot either bearing weight or in the upright pedal position, but occasionally oblique views are required with the horse standing on the x-ray cassette (e.g., dorsal 45°/proximal 45° lateral-palmarodistal medial oblique radiographic images). Separate centers of ossification at the palmar aspect of the palmar process should not be confused with a fracture.¹⁰ Rarely a palmar process fracture is seen only in a palmaroproximal-palmarodistal oblique radiographic image. Occasionally obscure incomplete, nonarticular fractures of the body of the distal phalanx are identified in a palmaroproximal-palmarodistal oblique view.

Nuclear scintigraphic examination usually is unnecessary for the identification of most acute fractures, except those causing episodic lameness, but can be helpful in confirming the likely clinical significance of older fractures.¹⁴ Scintigraphy also is useful for identification of subchondral bone trauma unassociated with detectable radiological abnormalities (see following text).

Although the majority of fractures of the distal phalanx are radiologically detectable, occasionally unusual configurations or locations have only been identified using MRI (e.g., an incomplete nondisplaced fracture on the axial aspect of a palmar process of the distal phalanx).¹⁵

Treatment and Prognosis

Conservative treatment of horses with nonarticular palmar process fractures, by box rest and use of a bar shoe with

five clips or bar rim shoe, has a good prognosis. Complete healing of the fracture may not be evident radiologically for several months, but most fractures eventually do heal. Horses with fractures extending into the medial or lateral extremity of the DIP joint also have a good prognosis with conservative management. The horse should continue to be shod with a bar shoe when work is resumed to reduce the risks of reinjury. If a bar shoe is replaced by an open shoe, avoidance of maximum work intensity may be preferable until the hoof capsule and distal phalanx have had time to adapt to altered concussive forces. Although sagittal and oblique articular fractures of the distal phalanx often heal well if treated conservatively in horses younger than 3 years of age, the prognosis for adult horses is more guarded, and internal fixation using a lag screw technique is recommended.^{1,7,9,12} Prognosis depends on whether displacement at the articular margin exists; displacement inevitably results in OA and associated lameness. Potential complications include postoperative infection and screw irritation or rejection. The use of a headless titanium Herbert cannulated screw (Zimmer Corp., Warsaw, Indiana, United States) may result in fewer complications.¹⁶ Complete fracture healing requires 6 to 12 months of convalescence with surgical management.

COMMINUTED FRACTURES

Comminuted fractures of the distal phalanx are not common^{1,2,7} but do occur occasionally. Many radiographic images may be required to establish the precise configuration of the fractures and determine possible articular involvement, which results in a more guarded prognosis. The configuration of the fracture determines whether internal fixation is a viable option.^{7,12}

FRACTURES OF THE DISTAL PHALANX ASSOCIATED WITH PENETRATING INJURY

A penetrating injury of the foot (see Chapter 28) may result in a fracture of the distal phalanx of any configuration. Treatment is dictated by the fracture configuration. The primary aim is to control infection. Removal of small bone fragments that otherwise may sequestrate may be preferable.

SUBCHONDRAL TRAUMA OF THE DISTAL PHALANX

Some horses have forelimb lameness, usually unilateral, associated with pain localized to the foot but no clinically significant detectable radiological abnormality. Nuclear scintigraphic examination reveals a focal round or semicircular area of IRU, seen in a solar image, either medially or laterally, far removed from the DIP joint, or on a lateral image in the center of the bone in a similar location to fractures.¹⁷ This lameness is believed to reflect subchondral bone trauma and is an injury that occurs particularly in racehorses in North America but also in other types of horses. Lameness usually is unaffected or, less commonly, only partially affected by intraarticular analgesia of the DIP joint. In some horses, mediolateral foot balance may be a predisposing factor. Less commonly the onset of lameness is associated with trauma. The failure to identify a fracture

radiologically may reflect the inherent limitations of radiography. Alternatively, such reactions may indicate that distal phalangeal fractures, especially in racehorses, may not be single-event episodes but rather the result of stress remodeling. Treatment comprises rest and correction of any mediolateral foot imbalance. Floating the heel of the affected side may be helpful. The prognosis is favorable given sufficient time, which is proportional to the duration of lameness before diagnosis and treatment. In horses with acute lesions a period of 6 to 8 weeks of box rest and controlled walking exercise usually is sufficient, with a progressive increase in work intensity thereafter; however, in those with more chronic lesions a longer period may be necessary, and repeated scintigraphic evaluation may be helpful to determine when the lesion is no longer active.

▣ PEDAL OSTEITIS: DOES IT EXIST?

Pedal osteitis strictly means inflammation of the distal phalanx and has long been suggested as a cause of forelimb lameness. However, it is a poorly defined condition, previously diagnosed radiologically, characterized by focal or general demineralization around the solar margin of the distal phalanx and widening of the vascular channels, with or without abnormal lucent areas in the palmar processes. It is now recognized that considerable variation exists in the radiological appearance of the distal phalanx in normal horses.¹⁻³ No good studies correlate foot conformation and the radiological appearance of the distal phalanx. It is my impression that those horses with a particularly thin sole, especially in association with a horizontal orientation of the solar margin of the distal phalanx, seem prone to foot soreness if worked regularly on hard ground, but the source of pain has been poorly defined. Radiological changes of the distal phalanx, once established, often persist over the long term and therefore are not synonymous with active inflammation. Radiographs represent a historical record of previous activity or injury. Scintigraphic examination of a large number of horses with foot pain occasionally has revealed evidence of abnormal bone turnover around the solar margins of the distal phalanx or confined to the palmar processes (see page 363).⁴ In those horses with IRU around the solar margin of the distal phalanx in solar views, correlation with other clinical signs and radiological findings frequently is poor unless the condition is localized to the toe, when it often reflects laminitis. The relevance of this finding in the absence of localizing clinical signs remains open to question because it also is seen in clinically normal horses. Pedal osteitis tends to have been used to describe a cause of lameness, when frequently the cause is actually undetermined.⁵ The cause of pedal osteitis has not been defined, although abnormal concussion has been suggested.

Therefore I suggest that the term pedal osteitis is inappropriate and should not be used to describe a cause of lameness on the basis of radiological findings alone. Nonetheless, a variety of radiological changes of the margins of the distal phalanx can be identified, the causes of which are poorly defined. With our current state of knowledge, attribution of lameness to these radiological changes seems inappropriate unless localizing clinical signs, or concurrent evidence of ongoing inflammation with or without abnormal bone turnover, are documented scintigraphically or

using MRI. Abnormalities of one or both palmar processes of the distal phalanx have been identified using MRI (see [Osteitis of the palmar processes of the distal phalanx](#)), with irregularity of the cortices and alteration of signal intensity, but only rarely have these been considered to be the primary source of pain causing lameness.^{6,7} There is an association between extensive ossification of the cartilages of the foot and trauma of the distal phalanx, usually involving the palmar processes.^{8,9}

Chronic laminitis may be associated with modeling of the toe of the distal phalanx and bone resorption with or without new bone on the dorsal aspect at the toe. Mineralization also has been identified on the dorsal aspects of the distal phalanx, midway between the coronary band and the solar margin; mineralization is seen best on lateromedial or slightly oblique radiographic images. This may represent mineralization in the dermal laminae or formation of new bone on the dorsal cortex of the distal phalanx. Extensive mineralization has been associated with lameness, but some roughening of the dorsal cortex in the region of the parietal sulci may be an incidental finding. Some horses with a clubfoot conformation develop focal loss of bone around the solar margin at the toe of the distal phalanx, as well as new bone on the dorsal aspect of the bone, associated with chronic lameness on hard ground. I suggest that in these conditions the radiological changes should be described and attributed to the primary cause rather than labeled as pedal osteitis. Many horses with poor foot conformation suffer chronic lameness, probably associated with abnormal concussion to both the soft tissue and bony elements of the hoof. Identification of the primary cause of the problem and admission that the precise source or sources of pain cannot be defined are preferable to use of the term pedal osteitis, which implies a definitive diagnosis.

▣ OSTEITIS OF THE PALMAR PROCESSES OF THE DISTAL PHALANX

ANATOMY

The palmar processes or angles of the distal phalanx are prism-shaped masses that project backward on the medial and lateral aspects of the bone. Each is divided into upper and lower parts by a notch or is perforated by a foramen that leads to the dorsal groove of the distal phalanx. The cartilages of the foot attach to the proximal border of each palmar process. In a normal horse, the solar and abaxial surfaces of the palmar processes are relatively smooth.

Osteitis of the palmar processes of the distal phalanx may be part of what has been called the “pedal osteitis complex,” related to the long toe–low heel syndrome. Its origin is poorly understood. It occurs almost exclusively in the forelimbs and may result in irregular roughening of the bone surface ([Figure 33-14, A](#)).

HISTORY AND CLINICAL FINDINGS

Lameness often is bilateral, insidious in onset, and tends to be worst on hard ground, similar to navicular disease. Affected horses often have poor conformation of the feet,

Fig. 33-14 • A, The distal phalanx of a horse that had chronic heel pain. The palmar process has a roughened surface, and new bone is evident on the solar surface. **B**, Lateromedial radiographic image of a foot of an 8-year-old Selle Français with recurrent heel pain. Note the orientation of the solar surface of the distal phalanx: the palmar process is lower than the toe, and the solar aspect of the palmar processes has an irregular contour. **C**, Dorsoproximal-palmarodistal oblique radiographic image of the same foot as shown in **B**. There is a very distinct trabecular pattern in the palmar processes, with many small lucent areas.

with low, collapsed heels. The sole may be very flat, thin, and readily compressible. If the sole is readily compressible, pressure applied with hoof testers may be resented, but this usually is not a localized response.

DIAGNOSIS

Diagnosis requires a combination of response to nerve blocks, radiography, and, ideally, nuclear scintigraphy and MRI.¹⁻⁷

Fig. 33-15 • A, Lateromedial radiographic image of a front foot of a 9-year-old Warmblood. Features include the abnormally elongated shape of the palmar processes, the horizontal orientation of the distal phalanx, and the thin sole. **B**, Solar scintigraphic image of the same foot in **A**. There is intense increased radiopharmaceutical uptake in the palmar processes of the distal phalanx.

Local Analgesia

Lameness is improved by perineural analgesia of the palmar digital nerves but generally is unchanged after intraarticular analgesia of the DIP joint or analgesia of the navicular bursa.

Imaging Techniques

Radiography

The orientation of the distal phalanx should be assessed in a lateromedial image. In a normal horse, the solar margin is smooth in outline and at a 5- to 10-degree angle to the sole, sloping proximally toward its palmar aspect.¹ In some affected horses the palmar processes are at the same level or lower than the toe of the distal phalanx (see [Figure 33-14, B](#)). The solar aspect of the palmar processes may have a fluffy appearance. The shape may change with elongation of the palmar processes; this change also is seen in dorsal 60-degree lateral-palmaromedial oblique or dorsal 60-degree medial-palmarolateral oblique images ([Figure 33-15, A](#)). In a dorsoproximal-palmarodistal oblique image, discrete circular radiolucent areas, 2 to 3 mm in diameter, may be visible in the palmar processes, or the trabecular pattern may be more obvious as a result of generalized demineralization (see [Figure 33-14, C](#)).

So-called *inversion* of the distal phalanx in hindlimbs, with the plantar processes lower than the toe, also has been seen in association with more proximal sites of pain causing

hindlimb lameness, such as proximal suspensory desmitis.^{2,3} I have not recognized this as a primary cause of hind foot pain.

Nuclear Scintigraphy

If the bony changes are active, nuclear scintigraphic evaluation may reveal IRU in the affected palmar processes to substantiate the relevance of the clinical and radiological findings (see Fig. 33-15, B). However, this is sometimes an incidental finding, and its clinical significance should be interpreted in light of other clinical observations. In a comparative radiographic, scintigraphic, and MRI study in 258 lame horses, IRU was more commonly seen in the medial palmar process of the distal phalanx than in the lateral palmar process.⁴ Focal IRU was overrepresented in palmar processes with MR abnormalities in signal intensity and was more prevalent in lame than nonlame limbs.

Magnetic Resonance Imaging

MRI may reveal increased signal intensity in one or both palmar processes in fat-suppressed images, sometimes with cortical irregularity and disruption of the adjacent laminar architecture. This is evidence of active osteitis and may be a cause of primary pain and lameness. However, it is common to see mild to marked reduced signal intensity in both T1- and T2-weighted images in the medial palmar process consistent with mineralization as either an incidental finding in a nonlame limb or coexistent with one or more other lesions that are more likely to be the primary cause of lameness.⁴

TREATMENT AND PROGNOSIS

Effective treatment depends on early recognition and corrective trimming and shoeing to try to restore more normal foot conformation. The response to treatment often is slow, and during the convalescent period, work on hard ground should be avoided. Horses with chronic lameness with a markedly distorted hoof capsule have a guarded prognosis. Some horses may benefit from removal of the shoes for 6 months and unrestricted exercise at pasture, provided that the hoof wall quality permits this approach and the ground is not excessively hard.

▣ DISEASE OF THE CARTILAGES OF THE FOOT

ANATOMY

The cartilages of the foot, also referred to as the *collateral cartilages of the distal phalanx*, *ungular (ungual) cartilages*, and *lateral cartilages*, originate as hyaline-type cartilage and become fibrocartilage in adults.¹ They attach to the proximal border of the palmar processes of the distal phalanx. The size and shape vary, as does the degree of ossification. The cartilages have axial extensions, and they seem to provide an internal support structure for the palmar (plantar) aspect of the foot.² An extensive network of venovenous anastomoses is present within the cartilages. Marked differences in the thickness and tissue composition exist in the front and hind feet. The cartilages of the foot

tend to be thicker in forelimbs than in hindlimbs, perhaps reflecting the greater weight-bearing capacity of the forelimbs.² The digital cushion has more fibrous or cartilaginous tissue in forelimbs than in matched hind feet, which have more adipose and elastic tissues. There may also be breed differences. An extensive and complex relationship exists between the cartilages of the foot and the digital cushion. The combined role is thought to be energy dissipation, which depends on hemodynamic flow.²

The cartilages of the foot are joined to adjacent structures by a variety of ligaments that vary in size and definition. The chondrocompedal ligament attaches the palmaroproximal aspect of the cartilage with the proximal phalanx, with an axial branch to the distal phalanx.¹ The chondrocoronal ligament connects the dorsal part of the cartilage with the middle phalanx.¹ Ossification of the lateral cartilage of the foot may be more extensive than the medial cartilage.^{3,5} The term *sidebone* has been used to describe extensive ossification of one or both cartilages of the foot. Ossification may occur from more than one center of ossification. Radiolucent lines between separate centers of ossification may persist throughout life (Figure 33-16).^{4,5} The degree of ossification is greater in mature horses than in horses younger than 2 years of age.³ Ossification tends to be more extensive in heavier breeds of horses than in lighter-weight horses. Extensive ossification is unusual in Thoroughbred and Warmblood breeds.⁵ Among Finnhorses, ossification was more common and extensive in mares compared with male horses,³ but no gender predilection was seen in a British study of mixed breeds.⁵ There is generally reasonable mediolateral symmetry in the degree of ossification of cartilages of the foot, with the lateral cartilage sometimes slightly more ossified than the medial. Marked asymmetry in ossification is unusual and may be a predisposing factor for lameness.⁶ There is generally greater radiopharmaceutical uptake at the base of the ossified cartilages than farther proximally, reflecting greater bone modeling, probably because of biomechanical stress.⁷

Fig. 33-16 • Dorsoproximal-palmaromedial oblique radiographic image of a foot of a mature riding horse. Lateral is to the right. Several centers of ossification of both the cartilages of the foot are present, more obvious laterally.

CLINICAL SIGNS AND DIAGNOSIS

The proximal aspect of the cartilages of the foot can be palpated proximal to the coronary band. However, palpation is an unreliable indicator of both the size of the cartilages and the degree of ossification. The degree of ossification can be established only by radiology. Lateromedial and weight-bearing dorsopalmar radiographic images are the most useful (Figure 33-17); however, additional information about modeling of the cartilages of the foot can be obtained from dorsoproximal-palmarodistal oblique and flexed dorsolateral-palmaromedial and dorso-medial-palmarolateral oblique radiographic images.⁸

Historically ossification of the cartilages of the foot has rarely been directly associated with lameness, although extensive ossification extending to the level of the proximal interphalangeal joint has been associated with a short-striding gait. However, there is now evidence that moderate to severe ossification of a cartilage of the foot may predispose to a fracture usually at the base of the ossified cartilage⁸⁻¹⁰ or osseous trauma of the distal phalanx distal to the ossified cartilage.^{6,8,9} Trauma at the junction between

separate centers of ossification can also be associated with lameness.^{6, 8,9}

There are usually no localizing clinical signs. Lameness is generally worse on a circle compared with straight lines, especially on a firm surface. Lameness is abolished by perineural analgesia of the palmar (abaxial sesamoid) nerves but is usually not substantially improved by intraarticular analgesia of the DIP joint.

Care should be taken not to confuse a radiolucent line between separate centers of ossification as a fracture. Nuclear scintigraphy may facilitate a definitive diagnosis of a fracture (Figure 33-18), trauma to the union between separate centers of ossification, and bone trauma of the distal phalanx.⁶⁻⁹ Diagnosis of bone trauma or some fractures at the base of an ossified cartilage is confirmed using MRI.^{6,8,9} These injuries can occur alone or together with injury of the ipsilateral collateral ligament of the DIP joint^{6,11,12} and/or the chondrocoronal ligament or the chondrosesamoidean ligament.^{8,9} There is an association between extensive ossification of the cartilages of the foot and injury of the collateral ligaments of the distal phalanx and distal phalanx trauma.^{8,9,12}

Fig. 33-17 • Lateromedial (A), dorsopalmar (B), and dorsoproximal-palmarodistal oblique (C) radiographic images of a foot of a 7-year-old cob gelding. There is extensive ossification of the cartilages of the foot. Medial is to the left. A separate center of ossification of the medial cartilage of the foot is seen in B. The horse had a previous fracture at the base of the lateral cartilage of the foot with smoothly outlined callus axially (arrows, C).

Fig. 33-18 • A, Dorsoproximal-palmarodistal oblique radiographic image of the right front foot of a Warmblood mare with severe lameness that partially improved with perineural analgesia of the palmar nerves at the base of the proximal sesamoid bones. The lateral cartilage of the foot is fractured. Dorsal (the right front foot is on the left) (**B**), lateral (**C**), and solar (**D**) scintigraphic images of the same foot in **A**. There is increased radiopharmaceutical uptake in the lateral cartilage of the right front foot.

Desmitis of the chondrocompedal, chondrosesamoid-eal, and chondrocoronal ligaments occasionally has been recognized in association with lameness.^{8,9,13} There are no localizing clinical features and MRI is usually required for diagnosis. Entheseous new bone on the distal diaphyseal region of the proximal phalanx reflects abnormal stress at the origin of the ligament between the apex of the cartilage of the foot and the proximal phalanx and

has been seen in association with extensively ossified cartilages.

Occasionally lameness has been associated with marked thickening of an unossified cartilage, hypervascularity, irregularity of the margins (especially abaxially), and increased signal intensity throughout the cartilage in fat-suppressed MR images, extending into the ipsilateral aspect of the distal phalanx.⁹

Chapter 34

Laminitis

PATHOPHYSIOLOGY OF LAMINITIS

Christopher C. Pollitt

A tough, flexible, connective tissue suspensory apparatus suspends the distal phalanx (DP) to the inside of the hoof wall. The surface of the inner hoof wall is folded into leaf-like lamellae (laminae) to increase the surface area of attachment between the hoof and the DP. A horse has laminitis when this attachment apparatus is compromised. Without the DP properly attached to the inside of the hoof, the weight of the horse and the forces of locomotion drive the DP down and away from the hoof wall. Arteries, veins, and nerves are sheared and crushed, and secondary to the lamellar pathology, the corium of the coronet and sole is damaged. Eventually even the DP itself may suffer deterioration and lysis of its dorsal margin. Unrelenting pain in the feet (bilateral forelimb usually) and a characteristic lameness occur. In acute laminitis the lamellar tissue suspending the DP from the inner hoof wall is affected at the

junction between the connective tissue of the dermis or corium (the bone side) and the basal cell layer of the epidermal lamellae (the hoof side). This junction, the basement membrane zone or dermal/epidermal interface, appears to be the weak link in an otherwise robust and reliable structure. Wholesale epidermal cell detachment from and lysis of the lamellar basement membrane may occur,^{1,2} leading to disruption of lamellar anatomy and ultimately compromise (to varying degrees) of the suspensory attachment between the DP and hoof. Associated with basement membrane lysis and dysadhesion are changes to lamellar epidermal cell morphology that result in lamellar stretching and attenuation. Thus whether by loss of basement membrane attachment or by lamellar stretching (or both), the DP draws away from the inner hoof wall and sinks downward. The degree of separation and sinking varies between horses affected with laminitis, ranging from barely detectable (mild) to catastrophically severe ("sinkers"). Ponies and small horses are usually less severely affected than their heavier cousins. A good correlation exists between the severity, as seen with the microscope (histopathology), and the degree of lameness (using the Obel grading system³) shown by the horse.¹ When a horse first shows laminitic pain, the anatomy of the hoof wall lamellae is already compromised. The higher the lameness grade, the more severe the microscopic damage. Any activity that places stress on an already weakened lamellar

attachment apparatus (such as forced exercise) exacerbates damage and is contraindicated. The use of nerve blocks to eliminate pain encourages locomotion and does more damage. Favorable outcomes are associated with effective preventive and early therapeutic strategies.

PATHOPHYSIOLOGY

Pathological deformation of the lamellar attachment apparatus begins during the developmental phase of laminitis. Tightly controlled metabolic processes are targeted, causing lamellar-specific pathology. One mechanism behind lamellar deformation involves lamellar enzymes. Enzymes are normal constituents of lamellar cells and respond to the stresses and strains of equine life and to constant growth. Sufficient enzyme is manufactured locally to release epidermal cell-to-cell and cell-to-basement membrane attachment as required, maintaining the correct shape and orientation of the lamellae. From time to time injury to the basement membrane requires its lysis and reconstruction. The controlled release of matrix metalloproteinases (MMPs) and specific tissue inhibitors of MMP (TIMPs) keeps repair and modeling in equilibrium.^{4,5} Normally the hoof lamellae slowly migrate distally past the stationary basement membrane that is firmly attached to the connective tissue covering the dorsal surface of the DP. Distal movement occurs because the hoof wall⁶ continually proliferates at the coronet and moves downward past the stationary DP by a process of controlled enzymatic modeling of the lamellar epidermis and the basement membrane zone. Accumulating evidence suggests that during developmental laminitis, compromise of the basement membrane zone occurs when production of constituent lamellar enzymes is increased and they are activated out of control. The enzymes known to be involved are metalloproteinase-2 (MMP-2), metalloproteinase-9 (MMP-9), membrane-type metalloproteinase (MMP-14), and aggrecanase (ADAMTS-4), and singly or together they destroy key components of the lamellar suspensory apparatus.⁷⁻¹⁰ A second, newly discovered lamellar deformation mechanism is seen in hyperinsulinemic horses. Experimental hyperinsulinemia is profoundly laminitogenic in ponies and horses, inducing clinical signs in 40 to 72 hours.^{11,12} Limited basement membrane dysadhesion occurred in insulin-affected horses but not to the extent seen in experimental carbohydrate-induced laminitis and was virtually absent in ponies. Mitosis, normally infrequent among lamellar epidermal cells, was a feature of hyperinsulinemic lamellar histopathology possibly contributing to lamellar lengthening.¹³ In laminitis induced by dosing horses with extract of Black walnut (*Juglans nigra*) heartwood, there was no evidence of basement membrane breakdown.^{14,15}

HISTOPATHOLOGY OF ACUTE LAMINITIS

Most descriptions of laminitis histopathology derive from laminitis induced experimentally with a single large dose of carbohydrate of either grain starch or oligofructose.^{3,16,17} The sequences of microscopic events that lead to clinical laminitis follow a consistent temporal pattern,¹⁸ and the stages of histological laminitis can be identified by the degree of severity of these changes. Making the lamellar basement membrane clearly visible is important and

Fig. 34-1 • Micrograph of normal hoof lamellae stained to highlight the basement membrane. The basement membrane (arrows) of each secondary epidermal lamella (SEL) is a magenta (black in the figure) line closely adherent to the SEL basal cells. At secondary dermal lamellae (SDL) tips, between the bases of each SEL, the basement membrane (BM) penetrates deeply (arrowheads) and is close to the anuclear, keratinized, primary epidermal lamella (PEL). The SEL tips are rounded (club-shaped). The basal cell nuclei are oval in shape (stars) and positioned away from the BM at the apex of each cell. The long axis of each basal cell nucleus is at right angles to the long axis of the SEL. The SDL are filled with connective tissue even at their very tips, between the SEL bases. These parameters of hoof lamellar anatomy form the basis of the histological grading system of laminitis histopathology. Stain, Periodic acid–Schiff; bar, 10 μ m.

requires staining lamellar tissues with periodic acid–Schiff (PAS) stain or with immunohistochemical methods using basement membrane–specific antibodies.^{1,2}

Normal lamellar anatomical characteristics, assessed before allocating a laminitis grade to a section of lamellar hoof tissue, are as follows (Figure 34-1):

- The tips of the secondary epidermal lamellae are always rounded (club-shaped) and never tapered or pointed.
- The basal cell nucleus is oval, with the long axis of the oval perpendicular to the long axis of the secondary epidermal lamellae. These parameters can be satisfactorily assessed using routine hematoxylin and eosin staining of sections.
- The basement membrane penetrates deeply into the crypts between the secondary epidermal lamellae and outlines the wafer-thin, but connective tissue–filled, secondary dermal lamellae.
- The basement membrane tightly adheres to the basal cells of each secondary epidermal lamella. The PAS or immunohistochemical stains show this best.

Grade 1 Histopathology

The earliest change attributable to laminitis is loss of shape and normal arrangement of the lamellar basal and para-basal cells. The basal cell nuclei become rounded instead of oval and take an abnormal position in the cytoplasm of the cell. The secondary epidermal lamellae become stretched, long, and thin, with tapering instead of club-shaped tips. These changes were present at 12 hours in serial lamellar biopsies taken after oligofructose dosing.¹⁸ First noticeable at the tips of the secondary epidermal lamellae, teat-shaped bubbles of loose basement membrane form. PAS staining shows this best (Figure 34-2).

Fig. 34-2 • Grade 1 histological laminitis (periodic acid–Schiff stain). Micrograph showing hoof lamellar tissues stained to highlight the basement membrane. The basement membrane (arrows) is stained dark magenta (black in the figure). At the now-tapered tips of the secondary epidermal lamellae (SELs), the basement membrane has lifted away (stars) from the underlying basal cells. Between the SEL bases the basement membrane (BM) is in its normal position, close to the primary epidermal lamellae; bar, 10 μ m.

Fig. 34-3 • Electron micrograph of hoof lamellar tip developing laminitis. The lamina densa (LD) of the basement membrane is separating from the plasmalemma of the lamellar basal cell (EBC). Some hemidesmosomes (black arrow) appear undamaged, but others (white arrow) have faded, are losing their anchoring filament attachments, and are drawing away from the basement membrane. Normally anchoring filaments (arrowhead) bridge the lamina densa firmly to the EBC. D, Dermis.

Examination of laminitis tissues with the electron microscope confirms lysis and separation of the lamellar basement membrane.¹⁹ Importantly, the greater magnification shows widespread loss of basal cell adhesion plaques (hemidesmosomes) and contraction of the basal cell cytoskeleton away from the inner cell surface. Electron microscopy shows why the basement membrane separates from the feet of the basal cells. The filaments that anchor hemidesmosomes to the lamina densa of the basement membrane no longer bridge the dermal/epidermal interface (Figure 34-3).¹³

Grade 2 Histopathology

Because the basement membrane is no longer completely tethered to the basal cells, it slips farther away with each

Fig. 34-4 • Grade 3 histological laminitis (immunostain). The basement membrane of a lamellar tip is highlighted by type IV collagen immunostaining. The tip of the primary epidermal lamella (PEL) has completely detached from its basement membrane. The PEL basal cells are now an unattached, amorphous mass. Collapsed tubes of basement membrane, now empty of epidermal cells, are still attached to connective tissue (arrowheads). The PEL has already moved 0.03 mm from its dermal compartment, and soon the distance will be measured, using a tape measure, on a radiograph. The inset shows a normal lamellar tip immunostained the same way. Type IV collagen immunostain; bars, 10 μ m.

cycle of weight bearing by the horse. Portions of the lamellar basement membrane are lysed initially between the bases of the secondary epidermal lamellae (see Figure 34-2). The basement membrane retracts from the tips of secondary epidermal lamellae, taking the dermal connective tissue with it. The basement membrane-free epidermal cells appear not to be undergoing necrosis, at least initially, and clump together to form amorphous, basement membrane-free masses on either side of the lamellar axis.¹

Grade 3 Histopathology

In laminitis the worst-case scenario is a rapid and near-total basement membrane separation from all the epidermal lamellae of the hoof toe, quarters, heel, and bars. Sheets of basement membrane peel away to form aggregations of loose, isolated basement membrane in the connective tissue adjoining the lamellae. The epidermal lamellar cells are left as isolated columns with little viable connection to the dermal connective tissue still attached to the DP. The hoof lamellar tips slide away from the basement membrane connective tissue attachments, at first microscopically, but as the degree of separation increases, the distance between hoof and DP becomes measurable in millimeters (Figure 34-4) and can be detected radiologically.²⁰ This manifests clinically as a sinker. Because the basement membrane is the key structure bridging the epidermis of the hoof to the connective tissue of the DP, wholesale loss and disorganization of the lamellar basement membrane follow and inexorably lead to the pathology of hoof and bone that characterizes the chronic stage of laminitis.

The laminitis process also affects the lamellar capillaries. As the basement membrane and the connective tissue between the secondary epidermal lamellae disappear, so do the capillaries. They become obliterated, compressed against the edges of the primary dermal lamellae. Without

a full complement of capillaries in the lamellar circulation, blood probably bypasses the capillary bed through dilated arteriovenous shunts,²¹ changing the nature of the foot circulation. A bounding pulse becomes detectable by finger palpation of the digital arteries. Furthermore, epidermal cell necrosis, intravascular coagulation, and edema are not universally present in sections made from tissues in the early stages of laminitis. The vessels in the primary dermal lamella, even the smallest, are predominantly open, without evidence of microvascular thrombi. The gross anatomical appearance of freshly dissected laminitis tissue is dryness. Sometimes the lamellae just peel apart.

Leukocytes, Inflammation, and Laminitis

It is rare to detect leukocytes in the lamellar tissues of normal horses.¹⁴ However, extravasation of leukocytes into the perivascular lamellar dermis occurs in carbohydrate-,¹ Black walnut extract-,^{14,22} and hyperinsulinemia-induced¹³ forms of laminitis. Because leukocytic infiltration of tissues is associated with inflammation, the discovery that leukocytic infiltration is common to most, if not all, forms of laminitis has reemphasized an inflammatory pathway to laminitis development. There is molecular evidence that inflammatory mediators may activate many of the processes known to damage the lamellar interface.^{23,24} Polymorphonuclear leukocytes are rich in MMP-9, and their presence within lamellar epidermal compartments in grade 3 histopathology¹ suggests that this basement membrane-degrading enzyme may have a pathological role in disease development. Also neutrophils produce reactive oxygen species and proinflammatory cytokines that probably contribute to cellular damage within the lamellar milieu.¹⁵ Lamellar damage and leukocyte infiltration are readily detected by calprotectin immunostaining,^{14,25} and because leukocyte infiltration precedes the expression of calprotectin in the lamellar epidermis, a role for leukocytes in initiating lamellar pathology has been suggested.^{22,23} However, carbohydrate-induced laminitis studied at the 12-hour postdosing time point shows basement membrane degradation occurring in advance of leukocyte infiltration, thus downplaying an initiating role for leukocytes in lesion development.²⁵

LAMINITIS THEORIES

The enzymatic theory of laminitis, based on the triggering of lamellar MMP activity,^{26,27} challenged the alternative view that laminitis was caused by ischemia and ischemia/reperfusion injury damaging epidermal lamellae because blood flow was impeded.²⁸ Evidence against ischemia/reperfusion involvement in Black walnut extract-induced laminitis came from studies measuring xanthine oxidase, a reactive oxygen intermediate that increases in tissues affected by ischemia and ischemia/reperfusion. Xanthine oxidase was absent in tissues with Black walnut extract-induced lamellar pathology, suggesting that a global lamellar hypoxic event had not occurred.²⁹ Furthermore, there is evidence from three independent international laboratories that the foot circulation during the developmental phase of both carbohydrate- and hyperinsulinemia-induced laminitis is vasodilated.³⁰⁻³³ Laminitis did not occur if the foot was in a state of vasoconstriction during the

developmental phase, suggesting that the trigger factors only cause laminitis if they reach the lamellar tissues at a high enough concentration and over a long enough time.³⁰ In current laminitis therapy there is a consistent lack of efficacy of drugs addressing ischemia, suggesting other pathogenic processes, such as inflammation, may be more important.

The actual trigger factors of laminitis remain unidentified. Gram-negative bacterial endotoxin has been detected in the circulation of horses with carbohydrate-induced laminitis³⁴ and is presumed to play a role in initiating lamellar pathology. Horses with colic, colitis, pleuropneumonia, and retained fetal membranes, the conditions often associated with laminitis development,³⁵ develop pyrexia and appear "endotoxic," but this is usually inferred from clinical signs rather than confirmed by endotoxin assay. Tumor necrosis factor and interleukin-6 (IL-6) along with other cytokines are expressed by mononuclear phagocytes within minutes of exposure to endotoxin.³⁶⁻³⁸ Decreases in digital blood flow and lamellar perfusion, secondary effects mediated by the platelet-derived vasoconstrictors 5-hydroxytryptamine and thromboxane, follow intravenous endotoxin administration.³⁷ However, laminitis or even foot pain has never been elicited by the experimental administration of endotoxin into either the bloodstream or the peritoneal cavity.^{39,40} Gram-negative bacteria disappear early, before the onset of clinical signs, from hindgut samples taken from horses developing carbohydrate overload-induced laminitis, suggesting no role for endotoxin in laminitis pathogenesis.⁴¹ Instead a plethora of absorbed microbial toxins may affect lamellar compromise, including gram-positive exotoxins from the explosive proliferation of hindgut streptococci after carbohydrate overload.

Lamellar disintegration of laminitis occurs well before clinical signs. The molecular conformation of the lamellar basement membrane is altered 12 hours after dosing with oligofructose, and a major constituent of the basement membrane, collagen IV, begins to disappear. Previously, damage to the lamellar basement membrane was attributed to MMP release and activation, but new evidence places MMP activation many hours later than other molecular events.²⁵ An enzyme capable of modifying the proteoglycan components of lamellar basement membrane is ADAMTS-4 (A Disintegrin And Metalloproteinase with Thrombospondin motifs), the gene for which has the greatest fold increase of any thus far discovered in laminitis development.^{10,25,42} ADAMTS-4 gene expression occurs early in laminitis development, and the gene product may play a central role in the pathophysiology of the disease.

Metalloproteinase Inhibitors

The activity of tissue MMPs correlates strongly with the degree of malignancy and invasiveness of lethal human tumors, such as malignant melanoma, breast cancer, and colon cancer.⁴³ Research in this field has generated a wide range of chemical agents capable of inhibiting MMP activity *in vitro* and *in vivo*. BB-94 (Batimastat, British Biotech, Oxford, England) blocks the activity of the laminitis MMPs *in vitro* and has the potential to be a useful tool in preventing and managing acute laminitis. Whether MMP inhibitors can prevent or ameliorate naturally occurring laminitis has yet to be established.

NATURAL TRIGGER FACTORS

Insulin

To test the hypothesis that hyperinsulinemia triggers laminitis, normal, lean ponies with no previous history of insulin resistance or laminitis were subjected to prolonged hyperinsulinemia and euglycemia.⁴⁴ All the ponies developed laminitis within 72 hours of hyperinsulinemia, a finding supporting the importance of insulin in the pathogenesis of endocrinopathic laminitis. Standardbred horses subjected to the same hyperinsulinemia/euglycemia clamp protocol also developed clinical laminitis but sooner (<48 hours) and with histopathology notable for lamellar basement membrane separation.³³ Hyperinsulinemia causes profound changes in the peripheral microcirculation,⁴⁵ and a vascular (ischemic) pathogenesis for laminitis has long been sought.⁴⁶ However, hoof wall surface temperature, measured continuously in the hyperinsulinemic and control horses, showed hyperinsulinemia induced early-onset, prolonged vasodilation. Lamellar insulin receptors are located within blood vessels (but not elsewhere) and in the presence of insulin activate vascular nitric oxide synthase to produce the potent vasodilator nitric oxide. Perhaps unregulated vasodilation results in excessive cellular uptake of glucose, lamellar glucotoxicity, and oxidative stress similar to that involved in the pathogenesis of atherosclerosis and the associated up-regulated MMP-9 activity in human diabetes.⁴⁷

Trigger Factors of Bacterial Origin

Equine lamellae, cultured in vitro, have tested resistant to virtually all known cytokines, tissue factors, and prostaglandins. Gram-negative bacterial endotoxin, extract of Black walnut (*J. nigra*), and even anaerobic culture conditions fail to induce lamellar separation or significant MMP activation.⁴⁸ Equine IL-6 added to cultured lamellar explants fails to activate lamellar MMPs or cause basement membrane disruption at the lamellar interface.²⁵ Some notable exceptions occur, however. Factors present in the supernatant of cultures of *Streptococcus bovis* (*S. bovis*) isolated from the equine cecum activate equine hoof MMP-2 and cause lamellar separation.⁴⁸ During carbohydrate overload, rapidly proliferating species of hindgut streptococci, predominantly *S. bovis* (now *Streptococcus lutetiensis*), ferment carbohydrate and produce large quantities of lactic acid.^{41,49,50} In the presence of virtually unlimited substrate, the population of *S. bovis* increases exponentially and then dies and lyses en masse. The liberated cellular components of lysed hindgut streptococci may cross the mucosal barrier of the damaged hindgut and reach the hoof lamellae hematogenously to initiate laminitis. Microbial and other factors probably associate with basement membranes throughout the body but probably only cause damage to lamellar basement membranes because of their uniquely equine involvement in weight bearing.

Equine Metabolic Syndrome

The term *equine metabolic syndrome* refers to horses with a history of laminitis, insulin resistance, cresty necks, and increased adipose tissue deposits in the withers, dorsal area of the back, and rump.⁵¹ Elevated serum insulin concentrations distinguish ponies that are susceptible to dietary pasture-associated laminitis.⁵²⁻⁵⁵ Furthermore,

insulin concentrations are markedly elevated in ponies that develop laminitis after grazing high carbohydrate pasture, whereas glucose, free fatty acid, and cortisol concentrations remain normal.^{53,56} In contrast to people, insulin-resistant horses rarely develop pancreatic exhaustion and hyperglycemia and are capable of producing exceptionally high serum insulin concentrations.^{56,57} Insulin toxicity appears to be a key factor in triggering equine laminitis. The onset of laminitis is associated with plasma insulin that exceeds 100 μ U/mL (normal range = 8 to 30 μ U/mL).⁵⁸

Horses and ponies at risk of laminitis should be blood tested for the early detection of hyperinsulinemia, and grain or other soluble carbohydrate should be withheld for 3 hours before testing. A single blood sample showing elevated insulin predicts that laminitis will occur or may become worse.⁵⁸ Techniques should be used to lower insulin concentrations and restore insulin sensitivity. A weight-reducing diet with a low glycemic index and physical exercise reduce insulin resistance in horses.⁵⁹ Insulin-sensitizing drugs of the type given to people with type 2 diabetes have been trialed in insulin-resistant horses. Metformin, at a higher dose than previously reported (15 mg/kg body weight per os [PO] every 12 hours), reversed insulin resistance during the first 6 to 14 days of treatment, but this effect diminished by 220 days.⁶⁰ Pharmacokinetic and epidemiological studies and placebo-controlled trials may further define the potential applications of this drug in the treatment of insulin resistance and prevention of laminitis.

Equine Cushing's Disease

Older ponies and horses sometimes develop a problem with their pituitary gland, which enlarges, becomes dysfunctional, and results in the development of equine Cushing's disease (ECD). Pituitary enlargement is sometimes described as a tumor (pituitary adenoma), but most affected horses have simply pituitary hyperplasia (an increase in size for unexplainable reasons). The region of the pituitary involved is the pars intermedia, giving the condition its common medical name: pituitary pars intermedia dysfunction (PPID). The dysfunctional pituitary produces an excess of hormones and peptides that control other hormones. A sign that horses are affected by PPID is hirsutism; the hair coat grows unnaturally long and is not shed at the usual times.

The hormone imbalance is associated with hyperinsulinemia that disturbs hoof lamellar metabolism, promoting an insidious, relentlessly developing, chronic laminitis. Affected horses and ponies often have higher than normal concentrations of glucose, adrenocorticotrophic hormone (ACTH), cortisone, and insulin in their blood. The levels of these substances vary throughout the day (diurnal or circadian rhythm), and care has to be taken with the interpretation of blood analysis. The clinical signs of ECD are pot belly and wasted top line, bulging supraorbital fat, polyuria and polydipsia, susceptibility to infections, and laminitis. Insulin status is a powerful prognostic indicator in horses with ECD, and insulin-resistant animals with a basal serum insulin concentration of greater than 188 μ U/mL are much more likely to develop laminitis and survive less than 2 years after diagnosis.⁵⁶ Laminitis that develops in association with ECD is usually refractory to treatment.

However, promising results have been obtained after the administration of pergolide mesylate (Permax, Valeant Pharmaceuticals International, Costa Mesa, California, United States), a drug registered for use in people. Doses in the range of 1 to 2 mg/horse/day have been recommended. The drug mechanism is to reduce production in the pituitary gland of the hormone (ACTH) that controls cortisol production in the adrenal gland. With cortisol under control, insulin responsiveness in hoof lamellae returns, and the laminitis stabilizes. Using pergolide mesylate, the ACTH concentration in horses with ECD decreases within 1 week.⁵⁸

Exogenous Corticosteroids and Laminitis

Although not proven experimentally, an association was made between systemic or intraarticular administration of corticosteroids, including triamcinolone acetonide (TMC) and methylprednisolone acetate, and the development of laminitis in otherwise apparently healthy horses.⁶¹ A single dose of TMC (0.05 mg/kg) given intramuscularly was cleared slowly and induced hyperglycemia and hyperinsulinemia for at least 3 days.⁶² Larger intramuscular doses (0.2 mg/kg) prolonged this hyperinsulinemic effect, and serum insulin concentration of around 130 μ IU/mL persisted for 6 days.⁶² However, none of the treated horses developed laminitis, although a “laminar” ring, coincident with the time of injection, grew down the hoof wall. In a retrospective clinical trial only 1 of 205 horses treated with TMC developed laminitis, and it had a previous episode of laminitis in its history.⁶³ Nonetheless, clinicians must be aware of the risks associated with exogenously administered corticosteroids. As Bailey and Elliot⁶¹ warn, “Glucocorticoids might only increase the risk of developing laminitis when other causative factors are present, or when the lamellar tissues are somehow ‘primed’ to undergo changes leading to cell damage and dysfunction.” A risk factor may be the preexisting hyperinsulinemia associated with metabolic syndrome or ECD. Because hyperinsulinemia alone will precipitate clinical laminitis,¹¹ injecting glucocorticoid into already insulin-resistant, hyperinsulinemic horses may elevate serum insulin concentrations into the laminitogenic range.

Supporting Limb Laminitis

Laminitis in the lamellae of a single hoof can occur whenever a horse's limb is forced to bear weight unilaterally for prolonged periods. This can occur when an injury (bone or joint fracture) or disease process (infectious arthritis) in the contralateral limb is so painful that weight bearing is impossible. After days to weeks of unrelieved weight bearing, the supporting limb develops lamellar pathology, often to a severe degree. Presumably the immobile limb lacks adequate lamellar perfusion and glucose delivery that eventually trigger a lamellar pathology indistinguishable from that initiated by other causes. Development of this form of laminitis may be delayed or prevented by supporting the limb by a firmly applied elastic support bandage and shoeing with an effective support shoe. The horse should be provided with a deep bed of wood shavings or sand so that it can lie down comfortably and allow blood to circulate through its feet. Deep, compliant bedding also allows the horse to find a foot position that promotes foot circulation. The injured limb should be treated promptly

and fitted with a cast or splint so that it can begin to take its share of weight bearing. Pain should be controlled with analgesics for the same reason. An exercise regimen of walking every 6 hours to encourage circulation of the contralateral foot has reduced the incidence of supporting limb laminitis in an equine hospital, but this practice may not be possible or advisable in all horses.⁶⁴

■ DIAGNOSIS OF LAMINITIS

Sue J. Dyson

Laminitis is characterized by an acute-onset lameness of variable severity involving one or more feet. Most often both front feet are affected, with or without the hind feet, but unilateral laminitis does occur, usually caused by excessive load bearing because of severe contralateral limb lameness. Occasionally the hind feet are affected, without involvement of the front feet. The horse may be extremely reluctant to move and, if persuaded to move, tends to land heel first, with a short, potterly gait, with the hindlimbs placed unusually far underneath the body. There is a marked shortening of the caudal phase of the stride at the walk. Lameness may be accentuated as the horse turns. Lameness is worse on hard ground than on soft ground. Although many horses show severe lameness, in those with milder lameness the lameness may be less typical, although suggestive of foot pain. When standing still the horse may position the hindlimbs unusually far underneath the body and may constantly shift weight between the limbs. A horse with severe primary lameness that has developed laminitis in the contralateral limb may start to load the originally lame limb, shifting weight between the two limbs.

Usually, but not invariably, a clinically significant increase in digital pulse amplitude occurs; however, in a thick-skinned cob-type horse this may not be palpable. In the acute phase the affected feet may be hot. Pressure or percussion applied to the feet, especially in the toe region, usually causes pain, but if the horn is excessively hard, the horse may not react. Careful palpation around the coronary band may reveal an unusual depression associated with sinking of the distal phalanx (DP). An area of unusual softness may herald infection tracking proximally in association with laminitis complicated by submural abscessation.

Clinical signs are usually diagnostic, except in less severely affected horses or those with involvement of only the hind feet, when the characteristics of the lameness may suggest foot pain, but not necessarily pathognomonic for laminitis. The response to perineural analgesia varies and is not associated necessarily with the degree of pain and lameness. Apparent desensitization of the foot with palmar (abaxial sesamoid) nerve blocks may have absolutely no effect on the lameness in some horses, although some improvement may occur in others.

Because laminitis frequently develops secondarily to a primary disease process, it is critical to evaluate the entire horse and to identify any predisposing factors that require treatment, such as endotoxemia, septic metritis, equine metabolic syndrome, or equine Cushing's disease. If equine metabolic syndrome is suspected, serum insulin concentrations and the response to an intravenous glucose tolerance test should be assessed. It has been suggested that the presence of three or more of the following may increase the

risk of laminitis development tenfold: insulin resistance, compensatory β -cell response, hypertriglyceridemia, and obesity (body condition score, $>6/9$).¹ Recent administration of corticosteroids may also be a risk factor; in a survey of 36 European sports horse practitioners, 12 had experienced the development of severe laminitis within 7 to 10 days of administration of corticosteroids in 22 horses.² Corticosteroids incriminated included dexamethasone, triamcinolone, and betamethasone administered either systemically or intraarticularly for treatment of recurrent airway obstruction, joint disease, or back pain, at what would be considered to be normal dose rates. The majority, but not all, of the horses were considered overweight. Approximately 50% of affected horses were humanely destroyed because of uncontrollable sinking of the DPs.

Radiographic examination is critical for establishing a treatment protocol and prognosis. Although rotation of the DP often can be managed successfully, sinking warrants an extremely guarded prognosis. Lateromedial images help to determine whether the condition is acute or an exacerbation of a more chronic problem. Abnormal thickness of the dorsal hoof wall, with or without modeling of the toe of the DP, implies previous disease. Lateromedial images are also important to establish the baseline position of the DP within the hoof capsule. Dorsopalmar images may be useful for assessing mediolateral balance in horses with chronic, unstable laminitis and to detect radiolucent lines indicative of lamellar separation (Figure 34-6, B). If the foot is grossly misshapen, trimming it first is preferable; otherwise, a false impression of severe rotation of the DP, which merely reflects the abnormal hoof wall growth and the development of a lamellar wedge, may occur.

Standardizing the procedure (positioning, film-focus distance, and exposure factors) is essential to make meaningful comparisons between examinations. If using conventional radiography, use soft exposures or radiographic film with a large gray scale to enhance soft tissue detail. A grid is usually unnecessary. A horizontal x-ray beam should be perpendicular to the sagittal plane of the digit, centered between the toe and the heel, about 2 cm distal to the coronary band. Radiodense markers are placed on the dorsal aspect of the hoof wall and on the sole at the apex of the frog. The marker on the dorsal hoof wall should extend from the coronary band distally. This helps to establish the orientation of the DP and its position relative to the coronary band. Radiological abnormalities include rotation or sinking of the DP, increased thickness of the dorsal hoof wall, and radiolucent lines in the dorsal hoof wall, reflecting serum, necrotic tissue, or gas caused by infection or hoof wall separation.

■ MEDICAL THERAPY OF LAMINITIS

Christopher C. Pollitt

Laminitis often develops because disease is occurring in a body compartment other than the foot. Thus it is of paramount importance that the primary disease is treated urgently and effectively. If the duration and severity of the primary disease can be reduced by intensive therapy, a strong chance exists that the severity of lamellar pathology also may be reduced, thus improving the prognosis for the horse. Severe laminitis is sometimes the outcome despite

the best of current therapy, but some horses can exhibit early, mild clinical signs of laminitis yet recover with no long-term ill effects.

Currently no drug regimen is able to arrest or block the triggering of laminitis, and the severity of the initial lamellar damage is what influences the outcome.¹ An effective laminitis preventive may emerge when the mechanism behind the disintegration of the anatomy of the hoof wall lamellae is fully understood. The discovery that enzymes appear to be involved in the lamellar failure of laminitis²⁻⁵ offers hope that proteinase inhibitor therapy, specifically targeted at hoof wall metalloproteinases, may arrest laminitis development. Horses that were able to keep the feet cool during the laminitis developmental period did not develop laminitis,⁶ an observation that was the basis for developing distal limb cryotherapy as a useful preventive, first-aid measure. Bacteria are a source of laminitis trigger factors⁷; therefore effective antimicrobial therapy is a treatment priority.

Horses diagnosed with toxemia during enteritis, colitis, strangulating colic, pleuropneumonia, retained placenta, infectious metritis, and grain overload are at high risk of developing laminitis, and medical therapy and mechanical support for the distal phalanx (DP) ideally should be initiated before the clinical signs of foot pain appear. Addressing laminitis as soon as it appears in a sick horse should always be regarded as an emergency procedure. Even then, treatment may be too late. Antiendotoxin hyperimmune serum (Polymune J, Veterinary Dynamics Inc., Templeton, California, United States) should be included in the intravenous fluid therapy for horses with, or at risk of developing, endotoxemia.

Nonsteroidal antiinflammatory drugs (NSAIDs) are given to reduce inflammation and foot pain. Flunixin meglumine (0.25 mg/kg thrice daily intravenously [IV] or 1.1 mg/kg twice daily IV) has a proven antiendotoxin effect by reducing prostaglandin production via cyclooxygenase inhibition^{8,9} and is valuable. Horses receiving flunixin meglumine that subsequently were given endotoxin had significantly lower blood prostaglandin and lactate concentrations and reduced clinical signs than control horses. However, the effectiveness of flunixin meglumine or any NSAID as an antilaminitis agent has never been tested. A proven cause-and-effect link between endotoxemia and laminitis has never been established.⁹

Phenylbutazone (4.4 mg/kg IV or PO every 12 hours) appears to be a potent NSAID for the control of foot pain and is popular with most clinicians. Phenylbutazone and flunixin meglumine at the lower dose rate can be used concurrently, the former to control severe foot pain and the latter to control the effects of endotoxemia. Intravenously administered ketoprofen (2.2 mg/kg twice daily) can be used interchangeably with flunixin meglumine. Horses with acute laminitis usually require NSAID therapy for at least 2 weeks, and because of its low cost, phenylbutazone (2.2 mg/kg) is the best choice for maintenance therapy. Care must be taken not to overdose small ponies.

However, NSAIDs were administered to horses during experimental induction of laminitis without altering the outcome; laminitis still occurred.¹⁰ When the laminitis process is triggered, virtually nothing by way of drug therapy stops its progress. The administration of phenylbutazone during the developmental and acute stages reduces foot pain and creates a more comfortable-looking

horse, but the disease continues unabated. This creates an ethical dilemma: balancing the need to alleviate pain and suffering against the realization that most of what is administered is only palliative. When NSAIDs are in use, the horse should be confined to a stall with deep bedding. Exercise is contraindicated while the horse is under the influence of analgesics.

CRYOTHERAPY

Distal limb cryotherapy to cool the feet, reduce lamellar tissue metabolism, and induce digital vasoconstriction is a proven preventive strategy when administered early in the developmental phase of laminitis. Cold-induced, digital vasoconstriction during the laminitis developmental phase may limit exposure to and impact of circulating trigger factors on lamellar anatomy. Cryotherapy may bestow additional protection by slowing the kinetics of lamellar enzyme activity below a threshold that causes damage. Nuclear scintigraphic studies showed cold therapy significantly decreased perfusion of the soft tissues of a horse's foot within 30 minutes of the application of external cold.¹¹ An ice water footbath was used successfully to treat a pony in the developmental stage of acute laminitis after experimental cecal catheterization.¹²

Two controlled studies testing the efficacy of cryotherapy for the prevention of laminitis were completed. In the first study,¹³ laminitis was induced in six horses using the oligofructose overload model. Each horse had one forelimb immersed in ice and water (mean temperature, 0.5 to 1.7°C) for a 48-hour experimental period, achieving a mean internal hoof temperature of 3.5 to 0.9°C. All horses developed clinical and histological laminitis in one or more of the untreated limbs. Laminitis did not develop in the treated limbs, and there was significantly reduced lamellar histological damage. In cooled limbs there was significantly less up-regulation of lamellar MMP mRNA compared with untreated limbs. Although cryotherapy markedly reduced the severity of laminitis, it did not completely prevent minor histological changes in four of the six horses. In the second study, cryotherapy was applied to all four limbs of six horses for 72 hours.¹⁴ Laminitis was induced as before, and the observation period was extended until 7 days after oligofructose dosing. The horses showed either no or very mild clinical signs of laminitis, and histological examination of lamellar tissues collected 7 days postinduction showed no evidence of laminitis. Control horses were lame at 7 days and had moderate to severe laminitis histopathologically.

Cryotherapy was instigated immediately after administration of the carbohydrate induction bolus in these studies. In a horse with grain overload or acute colitis such prompt initiation of cryotherapy may not be possible. It is unclear whether such a potent prophylactic effect would occur if cryotherapy was initiated later in the course of the disease when lameness was already present. However, the potential value of cryotherapy to prevent laminitis was demonstrated, and further clinical evaluation of the technique is justified.

Cryotherapy for laminitis requires maintaining the limbs from the proximal metacarpal region and distad in a slurry of crushed ice or a circulating cold water (1 to 4°C) apparatus continuously for 24 hours or even longer if the

period of septic shock, pyrexia, and digital vasodilation persists. Cryotherapy is safe, well tolerated, and economical. Unlike people, horses do not find cold therapy noxious. We have kept the forelimbs of normal horses in circulating, very cold water continuously for 3 days, with no immediate or long-term ill effect. Initial experiments support the effectiveness of cryotherapy for halting laminitis onset.^{13,14} Keeping a horse with its feet in ice and water requires an extraordinary amount of time and dedication but can be done and, if laminitis is prevented, is worth the effort.

DIGITAL BLOOD FLOW THERAPY

Vasodilatory therapy and hot water footbaths during the developmental phase of laminitis are contraindicated. Drugs with vasodilator action, such as isoxsuprine hydrochloride, acepromazine, and glyceryl trinitrate (applied as patches to the pastern), may be beneficial after lamellar damage has occurred, when healing is required, but should be administered with caution during the developmental phase of laminitis. However, neither orally administered isoxsuprine nor pentoxifylline produced significant improvement in digital or lamellar blood flow when tested under controlled conditions using ultrasound and laser Doppler flowmetry.¹⁵⁻¹⁷ Intravenously administered acepromazine maleate, long held to be effective at increasing lamellar microcirculatory blood flow, had no significant effect when tested by laser flowmetry.¹⁷ Glyceryl trinitrate tested in the same way, using a Black walnut extract laminitis induction model, had no effect on lamellar blood flow.¹⁶ The continued veterinary use of these drugs in the therapy of laminitis is questionable.

Exercise of an intensity that increases core temperature and local analgesia of the palmar or plantar nerves result in hoof wall heating (and by implication, vasodilation) and are contraindicated during the developmental stage of laminitis. Local analgesia of the foot to reduce foot pain and encourage the horse to walk may result in greater lamellar damage than in a rested, confined horse. Forced exercise of any horse with acute laminitis is strongly contraindicated.

FREE RADICAL SCAVENGERS

Dimethyl sulfoxide (DMSO) may be given intravenously for its free radical scavenging and antiinflammatory effects. DMSO (90% solution) mixed with polyionic solutions and 5% dextrose is best administered slowly at about 8 L/h. The concentration of DMSO must remain below 20% to avoid the risk of intravascular hemolysis. However, despite the potential value of DMSO, its promise as an effective laminitis therapy has not been fulfilled. Evidence exists that ischemia, reperfusion injury, and generation of free radicals are not involved in the pathogenesis of horses with laminitis induced with extract of Black walnut.¹⁸

RECOMMENDED TREATMENT STRATEGY

Cryotherapy is the frontline of defense against laminitis and should be instituted early, preferably before clinical signs of foot pain appear. Cryotherapy has a proven preventive effect when applied throughout the developmental period of carbohydrate-induced laminitis.^{13,14} Applied to all

four limbs during the developmental phase of laminitis, distal limb cryotherapy is an effective means of ameliorating the disease and is recommended in horses at risk of developing acute laminitis. Clinically, distal limb cryotherapy has been applied for up to 5 days and successfully prevented clinical laminitis in horses affected by acute colitis.¹⁹

The list of pharmaceuticals that have been administered to horses with laminitis is long, and, apart from the NSAIDs, none have achieved particular prominence. Aggressive treatment of the primary disease using fluids and electrolytes, antibiotics and NSAIDs, and uterine lavage for horses with infectious metritis or retained placenta is recommended.

The administration of 4 L of mineral oil four times a day may be beneficial in horses with laminitis developing from grain overload. Mineral oil has a laxative effect and is said to block the absorption of toxins in the large intestine.²⁰ Activated charcoal is an effective adsorbent of a range of toxins and may be useful in horses with grain overload if administered promptly. In Australia, doses of 1 to 5 g/kg/day have been used to treat plant toxicoses in large animals. The higher dose is indicated if a large quantity of grain has been consumed. However, activated charcoal has not been tested against alimentary laminitis; thus its true effectiveness is unknown. The application of cold therapy to all feet, strict confinement to a stall with a deep bedding of sand or shavings, and mechanical support for the DP are also recommended.

Laminitis developing secondary to equine Cushing's disease (pituitary pars intermedia dysfunction) is usually refractory to treatment unless horses are given pergolide mesylate (1 to 2 mg/horse/day) to reduce adrenocorticotrophic hormone (ACTH) production in the pituitary gland.²¹ Within 7 days of commencing pergolide treatment, plasma ACTH concentration and adrenal cortisol levels are significantly decreased and probably so is the associated hyperinsulinemia.²² Metformin (15 mg/kg body weight PO every 12 hours) reverses insulin resistance and decreases serum insulin concentration during the first 6 to 14 days of treatment, but the effect diminishes by 220 days.²³ Responses to insulin reduction strategies may be disappointing if substantial lamellar pathology already exists. Preventive use of pergolide and metformin, before or shortly after the first laminitis episode, may be more efficacious.

Some horses that show the clinical signs of acute laminitis recover completely if treated promptly using a combination of rational medical therapy and mechanical support. However, horses recovering from even the mildest form of laminitis should be observed closely and allowed to rest. If no radiological evidence of palmar displacement of the DP within the hoof capsule is apparent, and the digital pulse amplitude is not palpably exaggerated 48 hours after treatment has ceased, the horse can be returned to its usual function with caution.

If radiographs show displacement of the DP, then the prognosis must be more guarded. Horses with a mild increase in the distance between the DP and the dorsal hoof wall, with or without rotation of the DP, often make an apparent recovery and remain sound indefinitely. However, horses with marginally greater displacement and rotation of the DP make only partial recoveries and often have a history of intermittent lameness, especially after exercise. Histopathological examination of the hoof

lamellae of partially recovered horses showed a reduction in the number of secondary epidermal lamellae. Many of the secondary epidermal lamellae had distorted and abnormal shapes even several years after the initial episode of laminitis. Some secondary epidermal lamellae become isolated from the attachment to the primary epidermal lamellae and exist as isolated, unattached islands adrift in the lamellar connective tissue. If the surface area of the lamellae of the inner hoof wall is reduced after laminitis, the effectiveness of the lamellar-DP suspensory mechanism must also be reduced. Horses developing laminitis associated with substantial initial lamellar destruction, as manifest by radiological displacement of the DP, appear never to make a complete anatomical recovery and are prone to recrudescence episodes of laminitic foot pain.

Ultimately the prognosis is directly proportional to the severity and extent of lamellar pathology. Horses with more than 15 degrees of rotation, accompanied by distal displacement of the DP within the hoof capsule, within 4 to 6 weeks of the initial episode of laminitis have a poor prognosis. Prolapse of the DP through an already necrotic sole, accompanied by subsolar and sublamellar infection, usually occurs. Discharge of purulent exudate from the coronet and the heel is common. Osteitis and radiological evidence of lysis of the distal margin of the DP develop. Such horses require months of expensive supportive care and surgery, and although occasionally a horse does make a surprisingly good recovery, most suffer months of crippling foot pain and recumbency and eventually require euthanasia on humane grounds.

The road to recovery after a serious episode of laminitis is a rocky one. The extent of lamellar pathology lies hidden beneath the hoof wall, and we can only guess at what is really going on. Radiographs and the initial degree of pain expressed by the horse, often masked by analgesics such as phenylbutazone, give valuable clues. However, relentless sinking of the DP in the hoof capsule and involvement of all four feet make recovery unlikely.

■ CHRONIC LAMINITIS

Christopher C. Pollitt and Simon N. Collins

Following the acute phase of laminitis a horse may recover fully, with no long-term adverse effects on foot function, or can progress into chronic laminitis characterized by displacement of the distal phalanx (DP) within the foot.^{1,2} This occurs because the damage to the lamellar interface is so extensive that the suspensory apparatus of the distal phalanx (SADP) can no longer maintain the normal anatomical relationship between the hoof capsule, dermis, and DP, resulting in lameness (Figure 34-5).²⁻⁷

Continuous supportive foot management is necessary to minimize the debilitating effects.⁷ Affected horses are either chronic remissive laminitics (CRLs) or refractory exacerbative laminitics (RELs).^{8,9} Although CRLs are responsive to palliative treatment with nonsteroidal antiinflammatory drugs (NSAIDs), RELs are minimally responsive, and euthanasia is often the only option to relieve unrelenting pain. CRLs remain highly susceptible to recrudescence episodes of acute intense pain.^{7,9} Epidemiological estimates suggest that 50% of all acutely laminitic horses become chronic, and that 50% of these remain permanently lame.¹⁰

The anatomical dislocation of the DP, which can be detected radiologically as “rotation” or “sinking” (Figure 34-6), depends on the extent and localization of the lamellar pathology, the magnitude of the loads placed on the foot, the effect of treatment modalities used, and disease duration.^{2,7}

Fig. 34-5 • Sagittal section of a foot with severe chronic laminitis showing presence of a large lamellar wedge. The attachment between the distal phalanx (DP) and the dorsal hoof wall (DHW) has failed, and hoof and bone are now widely separated. The dotted line shows the original position of the DP. The angled black line shows that the DP has rotated around the distal interphalangeal joint (in the direction of the curved black arrow) and is no longer in alignment with the pastern axis (longitudinal axis of the proximal and middle phalanges), that is, phalangeal rotation. The material now between the inner aspect of the hoof wall and the DP is abnormal and consists of hyperplastic epidermal tissue that forms a weak, pathological structure called the lamellar wedge (straight black line). The distal descent of the unsupported DP within the hoof capsule has affected the normal alignment of the dermal papillae, resulting in distorted growth of the proximal hoof wall tubules, and has caused the sole to become convex instead of concave (dropped sole). Two dark hemorrhagic zones (white and black arrows) show the sites of greatest pressure and trauma.

Disease progression and exacerbation are associated with the initiation of a number of changes, including lamellar wedge formation (see Figure 34-5), bone modeling and lysis (particularly at the apex of the DP), and abscessation within the solar dermis.^{2,5,7,11,12} DP dislocation results in the development of vascular deficits within the coronary and solar plexi, as well as within the sublamellar and lamellar dermis.¹⁴ There is also alteration to the normal pattern of hoof horn production from the coronary, lamellar, and solar regions of the foot, which leads to the development of a distorted hoof capsule.^{2,7}

It is important to assess the nature and extent of DP dislocation because it relates directly to the degree of lameness,^{13,15} the likelihood of return to former performance levels,^{13,15,16} and survival outcome.^{13,16,17} The following anatomical variations in DP dislocation occur, relating to the site and extent of lamellar pathology^{2,7,18}:

1. Angular deviation between the dorsal aspect of the DP and the dorsal aspect of the hoof wall—ambiguously referred to elsewhere as capsular rotation
2. Phalangeal rotation—angular deviation between the dorsal aspect of the DP relative to the phalangeal axis
3. Distal displacement of the DP—distal displacement of the proximal aspect of the extensor process of the DP relative to the proximal aspect of the hoof wall (called sinking)
4. Combined phalangeal rotation and distal displacement of the DP
5. Asymmetrical distal displacement of the DP—occurring mainly on the medial or lateral aspect of the foot

With sinking of the DP there may be a depression palpable at the coronary band,^{2,7} which is focal or extends around the circumference of the coronary band.

Radiological examination is essential to determine the position of the DP. Extreme changes are readily appraised by visual inspection alone. However, subtle and modest changes require objective evaluation, especially when

Fig. 34-6 • **A**, Lateromedial radiograph of a catastrophic “sinker” foot, showing a visible and palpable supracorony depression (**A**), and compression and distortion of the coronary dermis between the hoof wall and the extensor process (**B**), following distal displacement of the distal phalanx (DP). A visible airline (**C**) provides evidence of failure of the suspensory apparatus of the DP and physical separation of the dermal and epidermal lamellae. The distal displacement of the DP has resulted in penetration of the apex of the bone into the solar dermis (**D**). **B**, Dorsopalmar radiograph of the sinker foot seen in **A**, showing a fine near-parallel array of radiolucent lines (**A**) indicating failure of the suspensory apparatus of the DP, as well as physical separation of the dermal and epidermal lamellae.

distal displacement of the DP occurs. Two parameters are of diagnostic importance: the hoof-DP distance and the coronary band extensor process distance.

In a normal foot, the perpendicular distance between the middorsal aspect of the hoof wall and the dorsal aspect of the DP (hoof-DP distance) is up to 18 mm,^{19,20} and the vertical distance between the proximal aspect of the hoof capsule and the proximal aspect of the extensor process of the DP is approximately 4 mm.²¹ These measurements do not take into account breed variation in foot size, and a better determination of DP dislocation may be if the hoof-DP distance exceeds 25% of the length of the palmar cortex of the DP.²⁰

Dislocation results in compression and shear within the solar dermis, as well as the development of foot pain detectable clinically as a positive response to the application of hoof testers.^{2,7} Recent work²² suggests that these events, combined with inflammatory responses, can induce neuropathic changes characterized by allodynia (pain from stimuli that are not normally painful) and hyperalgesia (lowering of the pain threshold). This results in a chronic pain state that is nonresponsive to traditional NSAID treatment.

DP dislocation may also be associated with vascular trauma occurring within the solar dermis, which subsequently becomes evident as hemorrhage within the sole horn directly beneath the solar margin of the DP.^{2,7} Lamellar pathology can result in the development of a “seroma” between the apical tips of the primary dermal lamellae and the basal region of the primary epidermal lamellae (adjacent to the inner hoof wall).² This seroma can be discerned as a mild linear reduction in radiopacity along the dermo-epidermal junction on lateromedial radiographic images optimized for evaluation of soft tissue (see [Figure 34-6, A](#)).

Progressive lamellar separation and inspissation of a seroma results in the appearance of a radiolucent airline seen in a lateromedial radiographic image^{7,11,23} or as a series of fine, near-parallel radiolucent lines in a dorsopalmar radiographic image (see [Figure 34-6, B](#)). The appearance of the airline indicates that extensive lamellar separation has occurred, and supportive foot management is required to stabilize the DP and protect the surviving lamellae. This may prevent further mechanical failure of the SADP and progressive dislocation of the DP. With continued hoof growth, the airline moves distally and eventually becomes evident at the weight-bearing border of the foot, providing a potential portal for secondary, opportunistic bacterial and fungal infection.

DP dislocation initiates a number of distinct secondary changes that further compromise foot function and alter the normal pattern of hoof horn production.^{2,7,11} Most notable is the development of a lamellar wedge (see [Figure 34-5](#)). The precise etiopathophysiological mechanisms that lead to its formation are not fully understood, and considerable variation in the histological appearance of this structure is reported.* This presumably reflects the progressive nature of the pathological processes that contribute to its formation over time, and the severity of the underlying lamellar pathology.

In mild laminitis, where lamellar separation is minimal, the lamellar wedge is characterized by elongation and

attenuation of the normal lamellar architecture.^{2,5} More extensive separation results in lamellar fragmentation and a permanent reduction in the SADP surface area of attachment.^{2,7} Hyperplastic epidermal proliferation occurs, and the resultant tissue has been described as “ectopic” white line¹³ because its histological appearance, a mixture of tubular and lamellar horn, resembles that of the white line.

The dislocation of the DP within the hoof capsule triggers a series of events that alter the physical appearance of the hoof capsule.^{2,7,8,22} These changes include a flattening of the sole in direct response both to the anatomical dislocation of the DP and from excessive movement of the DP occurring within the hoof capsule during weight bearing. This can cause vascular trauma of the solar dermis and lead to abscessation and the production of a false sole ([Figure 34-7](#)). In severe laminitis, the sole becomes convex, and the DP may eventually prolapse through it, which results in severe unrelenting pain and prolonged recumbency. Solar prolapse of the DP often results in the development of proliferative granulation tissue and associated subsolar abscessation at the site of the prolapse.

Elongation, attenuation, and separation of the lamellar interface become apparent on the solar surface of the hoof as a progressive “widening” of the white line,^{2,7,8} which may be accompanied by hemorrhage. Dislocation also leads to pathological alterations in the coronary band. A combination of compression, vascular deficits, and reorientation of the dermal papillae alters the normal pattern of hoof horn production. There is reorientation of the dermal papillae of the coronary band,^{7,28} which results in a realignment of the direction of horn growth at the midline of the hoof and leads to differential rates of proximal-distal hoof horn growth around the circumference of the hoof capsule. As a result, the growth rings diverge circumferentially from the dorsal aspect of the hoof wall to

Fig. 34-7 • High-resolution sagittal three-dimensional T1-weighted spoiled gradient-echo magnetic resonance image of a chronic laminitic foot, showing angular deviation between the dorsal surface of the hoof wall (viewed proximally) and the dorsal aspect of the distal phalanx (A); a linear hypointense area at the margin of the lamellar interface, indicating lamellar separation and/or seroma formation (B); ectopic white line of the lamellar wedge (high signal intensity within the lamellar interface) and the widened sublamellar dermis proximally (intermediate signal intensity) (C); double (false) sole (D); and track of solar abscessation passing through the widened white line at the hoof wall-sole junction (E).

*References 2, 5, 11, 13, 24-26.

the heel. If left unattended this leads to the development of a distorted hoof capsule, characterized by both an excessive buildup of heel horn and dorsal concavity of the hoof wall. With advanced lesions there is a physical separation, or shear lesion, of the hoof capsule from the underlying coronary dermis,² and if extreme this results in complete avulsion of the hoof capsule.^{2,7}

DP dislocation is often accompanied by progressive demineralization of the distal margin of the DP.^{2,7,11} Radiological abnormalities vary from low-grade demineralization and slight modeling of the apex of the DP (a “ski tip”) to extensive radiolucent defects on the distal, dorsal, and palmar cortices, as well as DP solar margin fractures. Extensive new bone formation may occur along the middorsal aspect of the DP, interpreted as a reactive response to increased levels of tensile stress occurring within the SADP.

There are also specific hidden dangers associated with DP dislocation that are only now being fully understood.⁷ The solar dermis may become distorted around the distal margin of the DP, causing a reorientation of the dermal papillae of the sole dermis in this region. This distortion changes the direction of sole horn production and leads to the development of an in-growing mass of sole horn that progressively impinges on the distal dorsal aspect of the DP and is often associated with pronounced bone lysis. In addition, a similar change in orientation can occur in the coronary papillae, and similarly leads to an in-growing mass of hoof horn, which further compresses the coronary dermis. Foot treatments should be instigated to reduce the risk posed by altered in-growing horn production. Timely resection of the proximal and distal dorsal hoof wall overlying the in-growing zones promotes reorientation of the dermal papillae, leading to normal hoof horn growth. Treatment shoes and sole inserts should support the palmar/plantar aspect of the feet and spare (relieve) any sole pressure beneath the dorsal margin of the dislocated DP. Shoe breakover should align with the DP dorsal margin to minimize strain within the lamellar interface.

DP dislocation can also adversely alter the normal pattern of blood circulation within the foot^{2,7} and thus affect foot metabolism, and is therefore of prognostic importance.

VENOGRAPHY

*Christopher C. Pollitt, Simon N. Collins,
and Greg Baldwin*

Venography is an additional method of assessing the damaged anatomical interrelationships within a chronic laminitic foot and the associated alteration to the digital circulation. The lack of valves in the digital veins distal to the midpastern region enables near-complete retrograde filling of foot veins with 20 to 25 mL of radiodense contrast media (Figure 34-8). The technique for venography is described elsewhere.^{1,2} Serial venography has diagnostic and prognostic value because it may detect the progressive soft tissue pathology associated with DP rotation, and it provides objective monitoring of the response to remedial foot management.

In venograms acquired before onset of laminitis the mean perpendicular distance between the dorsal aspect of the hoof wall and the dorsal aspect of the distal phalanx

Fig. 34-8 • Lateromedial venogram of a normal foot. Most of the vessels are large veins. Veins in the solar and terminal papillae are visible but not the lamellar veins and capillaries. The dorsal margin of the distal phalanx is proximal to the circumflex vein. CP, Coronary venous plexus; EP, extensor process of the distal phalanx; SLP, sublamellar plexus; TA, terminal arch vessels (arrow); DP, distal phalanx (distal margin arrow); TP, terminal papillae; CV, circumflex vein (arrow); SP, sole papillae. (Venogram from Homestead Equine Hospital, Pacific, Missouri, United States.)

Fig. 34-9 • Lateromedial venogram of a chronic laminitic foot, showing the presence of diffuse contrast agent (*feathering*) within the sublamellar dermis distally (A). Note the apex of the distal phalanx is at the level of the circumflex vessels dorsally.

(DP) (hoof–DP distance) is approximately 18 mm, and the width of the sublamellar venous plexus is 3.0 mm with a linear distance between the apex of the DP and the circumflex vessels of 8.0 mm. The apex of the DP is proximal to the level of the circumflex plexus.³

Chronic laminitis is associated with alteration of the venographic appearance that correlates to disease severity and progression (Figures 34-9 through 34-11). Within 7 days of the onset of experimentally induced laminitis, there is an increase in the hoof–DP distance of less than 2 mm. This is associated with a corresponding increase in the width of the sublamellar vascular plexus, with evidence of contrast media penetration into the sublamellar dermis. The apex of the dislocated DP is level with the circumflex plexus. There is reduced contrast medium filling within the coronary plexus as a result of compression of the dermal

Fig. 34-10 • Lateromedial venogram of a foot with recent-onset laminitis and mild rotation of the distal phalanx, showing complete venous deficit within the coronary plexus dorsally and the proximal region of the dorsal sublamellar plexus (A). The circumflex vessels dorsally have been distorted substantially around the apex of the distal phalanx (B), which is indicative of the hidden danger of an inward-growing solar horn. (Venogram from Davide Zani, University of Milan, Italy.)

Fig. 34-12 • Lateromedial venogram of the same laminitic foot as shown in Figures 34-10 and 34-11 following coronary band peeling and removal of the dorsal aspect of the hoof wall. This has resulted in restoration of venous filling within the coronary and sublamellar plexus (A). In addition, there has been realignment of the circumflex vessels at the apex of the distal phalanx (B) and a modest improvement of venous filling of the solar plexus (C). (Venogram from Davide Zani, University of Milan, Italy.)

Fig. 34-11 • Lateromedial venogram of the same laminitic foot as shown in Figure 34-10 following supportive farriery intervention. Foot trimming and remedial shoeing have resulted in the partial restoration of venous filling within the coronary plexus dorsally and the proximal region of the dorsal sublamellar plexus (A). However, a venous deficit has developed in the circumflex vessels dorsally (B), and the apex of the distal phalanx (C) has descended below the level of the circumflex vessels, resulting in a pronounced venous deficit in the solar plexus dorsally. (Venogram from Davide Zani, University of Milan, Italy.)

tissues between the extensor process of the DP and the proximal aspect of the hoof wall.

There may also be distortion of the circumflex plexus as pathological abnormalities of the solar dermis around the apex of the DP develop. Inward-growing lamellae (lamellar wedge) and distorted inward-growing tubular horn of the proximal hoof wall and dorsal sole further alter patterns of contrast media distribution.

With more severe DP dislocation, the increase in hoof-DP distance is greater than 4 mm, and the magnitude of the filling deficit in the coronary plexus increases. The apex

of the DP is distal to the circumflex plexus (see Figure 34-11). These events are associated with widening and distortion of the sublamellar and circumflex vascular beds. The sublamellar vascular bed increases in width with contrast medium penetration throughout the sublamellar dermis. The distance between the tip of the DP and the circumflex vessels also increases. Vascular filling deficits may also be evident within the distal, dorsal sublamellar plexus, evidence of an encroaching lamellar wedge and a prelude to DP lysis in this region.

Treatment of a chronic laminitic horse is aimed at stabilizing the foot, preventing further DP dislocation, and crucially restoring the circulation (Figures 34-11 and 34-12). Various treatment approaches have been suggested. These include rasping of the distal portion of the dorsal hoof wall and the dorsal aspect of the sole to relieve pressure on the circumflex vessels of the toe and to allow realignment of the solar plexus at the apex of the DP. The concurrent application of beveled, rocker, or reversed shoes may also help by reducing weight-bearing pressure in this region of the foot. Shoe breakover should be aligned with the dorsal distal margin of the DP to reduce strain within the lamellar interface. Complete or partial hoof wall resection, as well as paring of the lamellar wedge, is advocated to aid reinstatement of the sublamellar circulation (see Figure 34-12). Finally, coronary band hoof wall peels or deep coronary band grooving⁴ may be beneficial to relieve compression of the coronary dermis, and hence reestablish the coronary plexus circulation. In addition, this treatment option aids realignment of the dermal papillae and restoration of normal patterns of hoof wall growth.

Serial venography gives important information on the progression of chronic laminitis pathology that is not detectable by standard radiology. The venographic changes, detectable early in the chronic phase, are a reference point for assessing the success of supportive therapy or subsequent clinical deterioration (see Figures 34-10 through

34-12). If no contrast medium filling deficits develop and the width of the sublamellar plexus remains stable, a guarded prognosis is justified. Deficits in venous filling with contrast media reflect focal dermal compression by distorted, aberrant lamellar and tubular hoof growth. This can potentially be corrected with judicious, timely hoof capsule resections. Filling deficits may reverse if hoof capsule modification is successful.

▣ HOOF CARE OF A LAMINITIC HORSE

Frank A. Nickels

Hoof care in all phases of laminitis is extremely important. The goal is to reduce stress to the damaged lamellae by minimizing the distracting forces affecting the displacement of the distal phalanx (DP) (rotation or sinking). These distracting forces are the weight of the horse, the constant pull of the deep digital flexor tendon (DDFT), and the leverage on the toe of the hoof capsule. Nothing can be done about the horse's weight, but absolute stall rest can reduce the increased stress associated with movement. Some of the weight of the horse can be partially redirected away from the hoof wall in the resting horse by removing the shoes. Recruiting other parts of the ground surface of the hoof to bear weight can also reduce stress on the hoof wall with the use of particular bedding or sole pads. Elevating the heel reduces the stress on the DDFT. In horses with rapid rotation or penetration of the corium through the sole, a tenotomy of the DDFT^{1,3,4} was recommended to eliminate any pull on the DP. Finally, beveling (unweighting) the toe with a rasp helps increase ease of breakover, thereby decreasing the stress created by the leverage of the toe. Baseline radiographic examination is important to establish the relationship between the DP and the hoof capsule. I place both feet on two 8 × 13 × 18-cm wooden blocks that provide comfort to the horse, evenly weight the digits, and eliminate radiological distortion. There are linear radiodense markers embedded in the surface of the blocks. I also place small spherical radiodense markers at the dorsal aspect of the coronary band and at the apex of the frog and a linear marker on the dorsal aspect of the hoof capsule (Figure 34-13).

In the developmental phase of laminitis the goal is to recognize the possibility of disease and be prepared if the disease occurs. The goal is to prevent and/or minimize the distal displacement of the DP. This can be partially accomplished by transferring weight from the wall to the solar surface of the foot and by reducing the pull of the DDFT. If the horse is shod, the shoes should be removed carefully by rasping off each nail clinch, then removing each nail separately with a creased nail puller. This helps to reduce mechanical trauma, pain, and discomfort associated with shoe removal. The only hoof care necessary in this phase is to bevel (unweight) the toe with a rasp back to a point 2.5 to 4 cm in front of the true apex of the frog, depending on the size of the hoof (see Figure 34-13). In a normal horse, the frog can serve as a reference point for the tip of the DP, which is located approximately 1.9 to 2.5 cm dorsal to the apex of the frog (see Figure 34-13). Soft bedding materials such as wet sand or damp peat provide good support and relief, but they may be difficult and expensive to maintain.

Fig. 34-13 • Lateromedial radiographic image showing small, spherical radiodense markers at the apex of the frog and dorsal aspect of the hoof. There also is a wire imbedded on the surface of the wood block on which the foot is resting. Note that the toe of the hoof capsule has been unweighted (white arrowhead).

Alternatively, frog or sole pads can be used. Frog support using Lily pads (Nanric, Inc., Lawrenceburg, Kentucky, United States) or roll gauze taped to the frog was commonly used in the past but is being replaced by pads that adapt to the entire solar surface, providing more support and comfort to the entire foot. High-density foam is one of the most practical and economical methods for providing solar support. Sheets of 5-cm extruded foam, used for house insulation (Styrofoam Scoreboard, Dow Chemical, Midland, Michigan, United States), can be purchased at home centers or building supply companies. For foam application, stand the horse on small precut rectangular blocks of the foam insulation, and then cut and shape the block to the foot using a serrated bread knife, leaving 1.3 to 2.5 cm extending in front of the toe to prevent it from being pushed back as the horse walks. Attach the shaped pad to the foot with duct tape (Figure 34-14). The 5-cm extruded foam may be too thick for some horses or ponies with small feet, and sheets of 2.5- and 3.8-cm foam are more appropriate. In the developmental phase only one layer is usually necessary. Closed cell foam is also useful and is commercially available. These pads can be attached with duct or elastic tape (Elastikon, Johnson & Johnson Consumer Companies, Inc., Skillman, New Jersey, United States).

In the acute phase of laminitis the goal is to recognize the disease early and take appropriate actions to relieve the pain and provide support and comfort to minimize the effects of the disease. If the shoes have not been previously removed it is important to remove the shoes as atraumatically as possible, as outlined above, to provide solar support. In some horses it may not be possible to remove the shoes or it may aggravate the condition. Solar support can be accomplished with the shoe left in place in these situations. The only hoof care necessary is to unweight the toe if possible. Soft bedding materials such as wet sand or damp peat provide support and relief, especially for those horses from which the shoes cannot be removed.

In the acute phase of laminitis two layers of foam are used to provide support and elevate the heel. One layer is applied and is then removed after 24 hours when it becomes compressed. Ideally, this layer will compress evenly to

Fig. 34-14 • These four pictures show a horse standing on a precut block of foam (A), the foam pad trimmed (B), duct tape applied to the bottom of the pad (C), and the pad attached to the foot with duct tape (D).

approximately 2 cm. Remove the dorsal portion (from the apex of frog to the toe) of this pad to reduce the pressure over the most painful area of the sole. This trimmed pad and another foam layer are then attached to the foot with duct tape to raise the heel and provide more cushion to an area of the foot that can tolerate weight bearing (Figure 34-15). The foam pads should be replaced every 4 to 5 days or as needed. A commercial therapeutic boot system, Soft-Ride (Soft-Ride, Inc., Vermilion, Ohio, United States), which has a variety of orthotic inserts, provides support, relief from pain, and is relatively easy to apply. A commercial wedge pad system (Redden Ultimate, Nanric, Inc.) using rubber impression material (Advanced Cushion Support, Nanric, Inc.) is available and works very well in horses not getting adequate support from the foam insulation or other types of solar support (Figure 34-16). These commercial pads are taped or glued to the foot. The system combines a cuff with two attached, 5-degree wedge pads with a built-in dorsal to palmar breakover. The bottom wedge also has beveled edges for ease of medial to lateral breakover; this bottom wedge can be removed separately.

The goal of hoof care in the chronic phase of laminitis is to minimize further rotation of the DP. The following

principles should be used when preparing the hoof and selecting a therapeutic horseshoe: (1) the palmar aspect of the hoof should be supported using all structures (sole, bars, and frog, including the central and lateral sulci); (2) the sole should be protected by not removing any portion of the sole dorsal to the apex of the frog; (3) the hoof wall should be trimmed from the quarters to the heel only to realign the solar surface of the DP and the weight-bearing surface of the hoof; (4) the dorsal aspect of the hoof capsule should be protected by bringing the point of breakover back to a point 2.5 and 3.8 cm (depending on the size of the hoof) in front of the true apex of the frog; and (5) the heels should be raised to reduce the tension of the DDFT. Two of the goals of hoof care—realignment of the solar surface of the DP and raising the heel to reduce tension of the DDFT—seem counterintuitive. In a chronic unstable laminitic horse these two principles are necessary to reduce the tension of the tendon and provide comfort. In a chronic stable laminitic horse with only mild misalignment of the solar surface of the DP, raising the heel after trimming is not necessary. Specific hoof care management in the chronic phase depends on whether the condition is stable or unstable. In horses maintaining a stable

Fig. 34-15 • The drawing illustrates the trimming (*dashed line*) of a compressed foam pad (**A**), which is then added to new layer of foam (**B**) before attaching the two to the hoof with duct tape.

Fig. 34-16 • Redden Ultimate (Nanric, Inc., Lawrenceburg, Kentucky, United States) is a wedge system that can be attached to the hoof by a cuff (**A**) with special glue or adhesive tape. There are two 5-degree wedge pads (**B** and **C**) attached to each other with screws. The bottom pad (**C**) has round edges for ease of lateral to medial breakover. The arrowheads show how the system eases the dorsal to palmar breakover.

condition, trimming alone may be all that is necessary, carefully following the stipulated principles. Generally, the traditional therapeutic horse shoes (heart bar shoe, reverse shoe with a wedge, reverse shoe with frog support, and the egg bar shoe with a treatment plate) advocated for chronic laminitis may be beneficial only if the condition is reasonably stable. Horses with instability of the DP require horse shoes that are adaptable and more compatible with the goals of hoof care. There are a number of commercially made, aluminum rail shoes (EDSS, Penrose, Colorado, United States; Aluminum 4 Point Rail Shoe, Nanric, Inc.)

Fig. 34-17 • The Ovnick aluminum shoe (EDSS, Penrose, Colorado, United States) has interchangeable plastic rails (**A**). The shoe is specially machined to pull the point of breakover (*small arrows*) back. It is designed to set back from the toe of the hoof (**B**). Sole support is provided with rubber impression material (**C**).

(Figure 34-17) that provide the additional requirements for support. The new design of these shoes automatically pulls the breakover back, raises the heel, and provides palmar support. Ideally, the breakover should be close to the tip of the DP. A rubber impression material (Advanced Cushion Support, Nanric, Inc.) is used between the palmar structures of the sole and the shoes to provide support of the entire foot.

Horses with severe rotation and/or penetration of the sole usually have insufficient heel to realign the DP and the weight-bearing surface of the hoof by removing the heel alone. I have used a special shoeing technique to reestablish this relationship. A rubber impression material (Advanced Cushion Support, Nanric, Inc.) is used to provide the sole support and acts as a spacer between the weight-bearing surface of the hoof wall and the therapeutic shoe (Figure 34-18). These shoes cannot be attached to the hoof conventionally but rather are fastened to the hoof using an acrylic adhesive and fiberglass cloth (Equilox and Equilox Composite Cloth, Equilox International, Pine Island, Minnesota, United States). Routine clinical and radiological evaluations provide useful information to determine the horse's progress every 5 to 6 weeks when the shoes are reset. This is a difficult technique to perform and to keep the foot balanced without placing undue stress to the hoof capsule. An alternative to this technique is to apply synthetic polymer (Steward Clogs, EDSS) (Figure 34-19) or wooden fabricated shoes³ (Figure 34-20). The wooden shoe can be easily adapted to complement the realignment of the DP. The same principles for treating a chronic laminitic horse are applicable for the wooden shoes.

In horses with an unstable foot or feet exhibiting progressive rotation or penetration of the corium through the sole, a deep digital flexor tenotomy^{1,3,4} is recommended to reduce the active forces influencing separation of the

Fig. 34-18 • This drawing illustrates the special shoeing technique for realigning the foot when there is penetration of the sole by the corium. The components of this technique are plastic rails (1), the EDSS shoe (2), and cushion elastomer (3). The cushion elastomer is used as a spacer to keep the contact surface of the shoe parallel to the solar surface of the distal phalanx. The shoe is attached with a hoof acrylic and fiberglass cloth because it cannot be attached to the hoof conventionally (not shown).

Fig. 34-19 • The Steward clog. **A**, The toe of the shoe. **B**, The heel.

lamellae and DP on the sole in the next section. This procedure relieves pain, prevents or minimizes rotation, and allows reestablishment of the normal relationship between the solar surface of the DP and the weight-bearing surface of hoof. Severing the DDFT causes partial luxation and hyperextension of the distal interphalangeal (DIP) joint, as well as overloading of the superficial digital flexor tendon (SDFT). This abnormal joint position may cause palmar foot pain and usually results in osteoarthritis of the DIP joint. Severe overloading of the SDFT may result in damage to the tendon, ultimately resulting in a flexural deformity of the metacarpophalangeal joint. Postoperative management of these horses is important to prevent or minimize

Fig. 34-20 • An example of a wooden fabricated shoe. The front of the shoe is labeled **A**. The black arrowheads show how the system eases the dorsal to palmar breakover. The sides of the wooden shoe are beveled approximately the same as the dorsal aspect.

these complications. Shoeing is crucial for protecting the DIP joint and reducing the load on the tendons. The horse is shod with a slight flexion of the DIP joint with a shoe in which the heels are raised and extend palmarly about 1 to 1.5 cm. The treatment of these horses with complicated laminitis may take months or years to resolve, takes perseverance and a team commitment, and can be an emotional roller-coaster for the owners. Owners should be made aware of these realities.

▣ DEEP DIGITAL FLEXOR TENOTOMY FOR MANAGING LAMINITIS

Robert J. Hunt

Transection of the deep digital flexor tendon (DDFT) has been advocated in treatment of horses with chronic refractory laminitis.¹⁻⁴ The procedure initially appeared to have merit when used in horses with acute laminitis, but the long-term results were poor because of the severe and unstable nature of the laminitis.² The procedure attenuated pain, but most horses had ongoing displacement of the distal phalanx (DP) and suffered recurrent abscessation, and ultimately humane destruction was necessary.

The rationale for surgery is based on the biomechanical forces in the foot, which include the attachments of the dermal lamellae between the DP and the hoof wall, the downward vertical load through the bony column of the limb, the proximal palmar traction of the DDFT on the DP, the proximal pull of the common digital extensor tendon, and the digital cushion. The balance of these forces maintains a functional unit.

During a non-weight-bearing state, minimal force is imposed on the digit by the DDFT. When the limb is placed under load, the DDFT serves as a tension band and places shearing forces on the dorsal lamellae of the digit from its proximal palmar pull. The predominant force on the digit is the vertical load produced by the weight of the horse. Neither of these forces is necessarily detrimental under normal conditions; however, with compromise of the dorsal lamellae during laminitis, these forces result in distraction of the DP from the hoof capsule. The type and

extent of displacement of the DP are determined by the degree of laminar damage and the load placed on the foot.

The rationale for tenotomy is to reduce the proximal palmar pull of the DDFT on the DP and therefore to decrease the shearing forces on the lamellae of the dorsal aspect of the foot. Transecting the tendon also permits lowering the heel if indicated to allow more normal alignment of the DP. The procedure generally is considered a salvage procedure for breeding horses or horses not intended for athletic endeavors, although some horses have returned to successful athletic careers. The degree of damage associated with the laminitis, rather than the surgery, limits future soundness.

No clear-cut guidelines dictate when and if surgery should be performed. In general, surgery is reserved for horses with chronic recurring laminitis that suffer from periodic hoof abscesses and show distal phalangeal rotation and contraction of the hoof wall, minimal to no sinking (distal displacement), and can produce a reasonable dorsal hoof wall. Horses with acute laminitis with instability of the DP–hoof wall unit are not good surgical candidates. If tenotomy is performed, additional measures, such as transfixation casting, must be provided.

Tenotomy may be repeated with recurrence of clinical signs or with the development of a metacarpophalangeal joint flexural deformity subsequent to a midpastern tenotomy. Performing repeat tenotomy is easier after a mid-metacarpal tenotomy, although repeat tenotomy is also possible to perform following a midpastern tenotomy. I have performed repeat tenotomy of the DDFT numerous times in horses with chronic recurring pain associated with laminitis. Clinical improvement was seen after each procedure, although subjectively the effects were not as beneficial or prolonged as in the previous tenotomy. This may have been associated with progressive deterioration of the digit associated with laminitis or from adhesions of the DDFT preventing tension relief after transection.

Deep digital flexor tenotomy is performed in the mid-metacarpal or midpastern region (Figures 34-21 and 34-22). When performed in the midmetacarpal region, the tenotomy may be done with the horse standing, under local analgesia, or under general anesthesia. An audible pop often occurs once transection is complete. A 1- to 2-cm gap in the transected tendon ends is immediately palpable. The stab incisions do not require closure, but a firm pressure bandage is applied.

Fig. 34-21 • Deep digital flexor tenotomy can be performed in the metacarpal region in a standing horse or with the horse under general anesthesia. DDFT, Deep digital flexor tendon; SDFT, superficial digital flexor tendon.

Fig. 34-22 • Deep digital flexor tenotomy can be performed in the midpastern region with the horse under general anesthesia. DDFT, Deep digital flexor tendon.

A modification of this technique involves the use of self-fashioned “butter knife” malleable retractors. A 3-cm skin incision is made over the DDFT on the lateral aspect of the metacarpal region. Using blunt dissection along the dorsal and palmar borders of the DDFT, two planes are created for insertion of the butter knife retractors. Care is taken to exclude the neurovascular bundle from potential transection. The DDFT is sharply transected using a No. 10 scalpel, and the skin is closed in routine fashion.

Midpastern tenotomy is almost always performed with the horse recumbent, with the limb flexed to relax the DDFT (see Figure 34-22). Performing the procedure in a standing horse is possible if general anesthesia is prohibited, such as in a late-term pregnant mare. However, in a standing horse there is a higher risk of contamination of the surgical site, with possible involvement of the digital flexor tendon sheath (DFTS); therefore extreme caution should be taken.

It is mandatory to apply an extended and optimally elevated heel shoe in horses with midpastern tenotomy before or during surgery; an exception may be for horses with severe contraction of the hoof and surrounding soft tissues. The shoe should be worn for a minimum of 8 to 10 weeks to prevent luxation of the DIP joint. Although this shoe is not mandatory for all horses with midmetacarpal tenotomy, if clinical evidence exists of DIP joint luxation, an extended and elevated heel shoe should be applied. After tenotomy a horse should be confined to a restricted stall-size area. Bandages should be changed every 2 to 4 days for 8 to 10 weeks to minimize swelling.

Depending on the solar angle of the DP, the heel may be lowered to facilitate alignment, but in feet with extreme contraction, changes should be made gradually. Relative “unloading” of the dorsal aspect of the foot may be accomplished by shifting the breakover in a palmar direction.

The amount of tension release is greater after midpastern tenotomy because of the anatomical approximation to the insertion of the DDFT on the DP and unrestricted separation within the DFTS. The tendon may separate 6 to

10 cm after transection in this region. In contrast, separation after midmetacarpal tenotomy is limited by peritendon attachment to the subcutaneous tissue.

Clinical improvement is generally seen within 2 to 3 days of surgery. In general, clinical effects after tenotomy appear to be beneficial for several months. A flexural deformity of the metacarpophalangeal joint may develop from chronic pain, resulting in unweighting of the limb and contracture of scar tissue at the tenotomy site. Chronic pain may result from overloading the superficial digital flexor tendon before healing, osteoarthritis of the DIP joint, or chronic infections of the digit. Chronic infection may be a major complication, especially if infectious osteitis of the DP develops. Systemic antibiotics, local debridement, topical antimicrobial drugs, and bandaging are important in resolving infection. Treatment of such complicated conditions may take many months to resolve at great emotional and financial cost, and everybody involved must be aware of this.

▣ OTHER MANAGEMENT ASPECTS OF LAMINITIS

Sue J. Dyson and Mike W. Ross

Medical management of laminitis (see page 372) and some aspects of hoof care focused on a horse with progressive rotation of the distal phalanx (DP) (see page 379) are discussed elsewhere. This section discusses some additional aspects of management, routine care, monitoring of the horse, and prevention of recurrence. It must be acknowledged that in equine practice, ideal management is not always possible, and compromises must sometimes be made to adapt to the prevailing circumstances.

In a horse with acute laminitis, some clinicians favor removal of the shoes, assuming that the horse can stand on soft bedding. However, in our experience, removal of the shoes often results in increased discomfort, and in the

acute stages of laminitis, we prefer to leave the shoes in place. Alternatively, the normal shoes may be replaced with glue-on heart bar shoes, foam pads, frog pads, or custom-made boots,¹ which seem to enhance comfort. Not all affected horses develop rotation or sinking of the DP; however, even if baseline radiographs reveal no evidence of rotation, each horse should be monitored carefully. If there is any evidence of increased discomfort, the feet should be reexamined radiologically. The client must be instructed carefully about observing the horse's stance and the frequency of shifting weight between limbs, mobility, and the amount of time spent lying down, as well as advised that veterinary advice should be sought if there is any evidence of deterioration.

Ideally a horse with acute laminitis should be restricted to stable rest, but this is not always possible, especially for a child's pony that lives outdoors throughout the year. In these circumstances, a small area of the field should be fenced off using electric fencing. This area should be tightly mown, and the grass clippings should be removed. Spreading a thick layer of wood shavings over the entire surface may be beneficial.

Many horses and ponies that develop laminitis are grossly overweight, and reduction of body weight is crucial for successful management. Owners are often reluctant to admit that the horse is overweight and find it difficult to restrict the diet adequately. It is helpful to weigh the horse or make an estimate of body weight using a height-specific weight tape² and then set a target for the expected weight loss with monitoring at intervals. Strict instructions concerning dietary management should be made, stipulating the amounts of food, preferably by measured weights, that should be fed. Horses should receive a maximum of 7 MJ/kg dry matter equivalent to poor quality hay. Hay should be soaked for a minimum of 12 hours to reduce soluble carbohydrates. Concentrate foods and other glycaemic foods, such as apples and carrots, should be eliminated; however, supplementation with vitamins C (5 mg/kg) and E (4 IU/kg) is potentially beneficial for their antioxidant effects. Low-energy chaff or small quantities of nonmolassed sugar beet pulp is acceptable. If a pony lives outdoors and cannot be stabled, then a strip grazing system should be established; each strip should be finely mown before the pony has access to it. A grazing muzzle may also be useful. If a horse has clinical evidence suggestive of equine metabolic syndrome, combined with increased serum insulin concentrations and an abnormal response to an intravenous glucose tolerance test, then oral administration of metformin (15 to 17.5 mg/kg PO twice daily), an insulin-sensitizing drug, is recommended, although clinical efficacy is not yet proven, and there are questions concerning bioavailability.³ Serum insulin levels should be measured episodically.

In horses with chronic laminitis, even if rotation of the DP occurred previously, the position of the DP may actually be stable. The heel tends to grow more quickly than the toe, and regular trimming of the heel and shortening the toe are imperative to try to reestablish correct alignment of the DP within the hoof capsule and relative to the phalangeal axis. It will take weeks to months to reestablish these alignments, and it is critical that this is a slow, deliberate process without using aggressive angle changes. The heart bar shoe recruits part of the frog to share load bearing, and if correctly fitted, it shifts weight-bearing load away

from the toe, thus sparing the dorsal structures of the foot. This approach, combined with removal of the lamellar wedge, often results in improved comfort and alignment of the hoof wall and DP. Correct positioning of the frog support plate is critical so that even, mild pressure is applied over the length of the frog. Reverse shoes or W shoes (open toe shoe with a heart bar) nailed on with one or two nails both medially and laterally, or glued or taped in place, may provide comfort in some horses. Often what works in one horse may not work in another, and a different strategy must be used. It may be necessary to obtain follow-up radiographs at 2-week intervals to determine whether additional trimming is necessary.

The term *derotation* of the DP has become popular; however, we believe that this is an inappropriate term. Although lowering the heel changes the angle of the DP with respect to the middle phalanx, it cannot acutely change the position of the DP relative to the hoof wall. The position of the DP within the hoof capsule often appears improved after removal of excessive toe.

It is critical for the farrier and veterinarian to work together closely. Although in general a slow deliberate approach to trimming is used, if the veterinarian believes that the farrier is not trimming the foot sufficiently aggressively, obtaining lateromedial radiographs may be helpful to demonstrate excess toe, heel, or both, as well as the position of the DP relative to the dorsal hoof wall and the phalangeal axis. Lateromedial radiographs are also useful for demonstrating excessive separation of the dorsal hoof wall or accumulation of fluid, as well as for determining when limited dorsal hoof wall resection may be indicated. If sinking of one or more of the DPs is evident radiologically, the owner must be advised that the prognosis for recovery is extremely guarded.

If pain is not adequately controlled by systemic analgesics, daily monitoring of the horse, preferably by a veterinarian, is crucial to identify signs of impending penetration of the sole, such as increased softening of the sole dorsal to the apex of the frog and red discoloration. The coronary bands of all feet should be assessed carefully; depression at the coronary band may herald sinking of the DP. Increased lameness may be associated with a subsolar abscess that requires establishment of drainage. A horse that has developed or is at risk of development of mechanically induced laminitis because of a painful condition in the contralateral limb must be monitored particularly vigilantly. In these horses, subtle evidence of mechanical laminitis is easily missed and usually occurs between 4 and 6 weeks after injury to the contralateral limb. However, in some horses, usually racehorses, mechanical laminitis occurs early, even within the first few days, and is inexplicable. Often the first sign of contralateral mechanical laminitis is increased weight bearing on the injured limb, or treading. Increased weight bearing on the injured limb may be a sign of improved comfort, but the clinician should investigate the contralateral limb carefully for the development of mechanical laminitis. Chronic laminitis may be associated with neuropathic pain, which responds poorly to nonsteroidal antiinflammatory drugs.⁴ Treatment with gabapentin (2.5 to 5 mg/kg PO twice daily) may improve comfort^{5,6}; however, the horse is likely to appear constantly drowsy, and to date there are no long-term data that document any long-term efficacy of this treatment.

Careful assessment of digital pulse amplitudes and foot temperature may be useful for detecting the development of laminitis or deterioration of preexisting laminitis. In older horses in which laminitis cannot be stabilized, consideration should always be given to the existence of primary equine Cushing's disease, which must be treated appropriately.

It is critical that clients be kept well informed of the likely outcome and are well apprised of the long convalescent periods that often are required after substantial rotation of the DP occurs. They must be warned that unexpected relapses may occur despite steady progress. Clients must be aware that the prognosis is hopeless in some horses, and euthanasia may be required. Humane decisions

for euthanasia can be difficult. Nonetheless, it is important to recognize that with early aggressive treatment some horses can make a complete recovery to athletic function despite marked rotation of one or more DPs. The prognosis is generally more favorable in ponies than in horses. Clients must be advised that continued long-term dietary management may be crucial to prevention of recurrent laminitis.

The prognosis in heavy breeds of horses with sinking of the DPs is generally hopeless. These horses seem particularly prone to the development of laminitis secondary to retention of the placenta, and although with aggressive management they can be salvaged until the foal is weaned, longer-term treatment is invariably unsuccessful.

The Forelimb

Chapter 35

The Proximal and Middle Phalanges and Proximal Interphalangeal Joint

Alan J. Ruggles

ANATOMICAL CONSIDERATIONS

The term *pastern* originated from the shackle that was secured below the metacarpophalangeal or metatarsophalangeal joints to tether a horse to the pasture.¹ The proximal interphalangeal (PIP) joint or pastern joint is a diarthrodial joint, which is formed from the distal aspect of the proximal phalanx and the proximal aspect of the middle phalanx. The pastern region is bounded dorsally by the common digital extensor tendon and on the palmar/plantar border by the distal sesamoidean ligaments, digital flexor tendons, digital flexor tendon sheath (DFTS), and the proximal and distal digital annular ligaments. The superficial digital flexor tendon (SDFT) inserts on the distal palmar/plantar aspect of the proximal phalanx and the proximal palmar/plantar aspect of the middle phalanx. The straight sesamoidean ligament arises from the base of the proximal sesamoid bones (PSBs) and extends distally to insert on the proximal palmar/plantar aspect of the middle phalanx. The oblique (middle) sesamoidean ligaments arise from the base of the PSBs and attach to the triangular region on the palmar/plantar region of the middle portion of the proximal phalanx. The medial and lateral collateral ligaments of the PIP joint provide support in the sagittal plane and attach to the collateral tubercles of the distal aspect of the proximal phalanx and proximal palmar/plantar aspect of the middle phalanx. The paired smaller abaxial and axial ligaments are located just palmar/plantar to the collateral ligaments. The neurovascular bundle of the digit runs just abaxial to the deep digital flexor tendon on the medial and lateral sides.

The palmar/plantar eminence of the middle phalanx extends proximal to the horizontal axis of the joint surface and blends proximally with a fibrocartilaginous cap at the most proximal extent of the middle phalanx. In the adult horse this is dense, and it is important to engage this portion of the bone during internal fixation of fractures or arthrodesis procedures.

The proximity of the pastern region to the ground, the paucity of soft tissue coverage over the dorsum and sides, and the important soft tissue structures on the palmar/plantar surfaces make it especially vulnerable to external trauma. Wounds in this region may involve the DFTS and warrant careful investigation. Angular deformities from growth disturbances at the pastern are uncommon but do occur. More commonly, deformities arise from physeal abnormalities of the distal aspect of the third metacarpal/metatarsal bones affecting the metacarpophalangeal/metatarsophalangeal joints. Radiological closure of the proximal physis of the proximal and middle phalanges occurs by 6 to 9 months of age, but functional closure is earlier, usually by 8 weeks of age. Radiological closure of the distal physis of the proximal phalanx occurs by 1 month of age. Radiological closure of the distal physis of the middle phalanx occurs by the time of birth.²

LAMENESS EXAMINATION

Physical derangements usually are obvious because of minimal soft tissue coverage of the pastern. Phalangeal fractures usually are associated with soft tissue swelling and focal pain. Effusion of the DFTS is typical of penetrating wounds of the sheath, damage to the enclosed digital flexor tendons, or injury of the sesamoidean ligaments located dorsal to the sheath. In horses with osteoarthritis (OA), new bone formation on the dorsomedial and dorsolateral aspects of the PIP joint often occurs, causing obvious swelling around the joint. Angular deformity of the digit with limb shortening often is present in horses with complex fractures of the proximal or middle phalanx. Effusion in the metacarpophalangeal or metatarsophalangeal joint is common in horses with fractures of the proximal articular surface of the proximal phalanx.

Lameness from the pastern region ranges from severe to subtle depending on the injury. Generally, disorders involving the PIP joint or DFTS cause obvious lameness, but lameness from early OA of the PIP joint may be mild, and the clinical signs and blocking pattern may be confused with foot or occasionally fetlock lameness. Pain in the pastern region may be exacerbated by distal limb flexion. There is often a weight-bearing lameness that is worse if a horse is lunged or trotted with the affected limb on the inside of a circle.

Response to intraarticular analgesia varies depending on the injury, but improvement of lameness by 50% or more implicates the PIP joint as an important source of pain. Entry into the PIP joint can be difficult, especially if new bone is present as a result of OA. Techniques for intraarticular and perineural analgesia are described in

Chapter 10. Complete analgesia of the PIP joint is not always accomplished by perineural analgesia of the palmar nerves at the level of the PSBs, and a low four-point (palmar and palmar metacarpal nerves) block may be necessary. However, in some horses lameness improves with palmar/plantar digital analgesia. Intraarticular analgesia of the PIP joint should be considered in a horse with suspected metacarpophalangeal or metatarsophalangeal joint pain that has not responded to treatment. Complete analgesia of the DFTS requires intrasynovial or a low four-point block. Localization by perineural analgesia to the pastern joint does not limit the source of the lameness to the joint itself. Injury to the soft tissue structures should be carefully evaluated if radiological examination reveals no clinically significant abnormalities.

IMAGING CONSIDERATIONS

Standard radiographic examination for evaluation of the proximal phalanx includes lateromedial, dorsopalmar (plantar), dorsal 45° lateral-palmaromedial oblique, and dorsal 45° medial-palmarolateral oblique images. Oblique radiographs that are angled distally are helpful to identify osteochondral fragments on the proximal palmar/plantar aspect of the proximal phalanx.³ If a sagittal plane fracture of the proximal phalanx is suspected, dorsopalmar/plantar radiographs that are 5 degrees medial or lateral to the mid-sagittal plane are useful. Slight underexposure of a lateromedial image helps to identify callus on the proximodorsal aspect of the proximal phalanx associated with chronic, short, incomplete fractures. Radiographic examination of the PIP joint includes lateromedial, dorsopalmar/plantar, and oblique images. Flexed oblique images are particularly helpful for evaluation of the articular margins.³ A well-positioned and exposed dorsopalmar/plantar image may reveal subtle joint space narrowing and increased radiopacity of the subchondral bone consistent with early OA. Comparative views of the contralateral limb may be helpful.

Contrast radiography may be used to determine the course of fistulous tracts or to identify communication between wounds and the DFTS or areas of proliferative synovium within the DFTS. Contrast radiography is performed by placement of a 50% solution of diatrizoate preglumine and diatrizoate sodium (Hypaque-76, Nyromed, Princeton, New Jersey, United States) within a draining tract or directly into the synovial structure after aseptic preparation. Standard radiographs are obtained to identify communication with draining tracts or filling defects.

Computed or digital radiography is helpful in detecting subtle changes in trabecular bone architecture and opacity and is the present state of the art for radiographic examination. Computed tomography (CT) of the distal aspect of the limb offers detailed information regarding structural injury to the bony column of the digit that may not be apparent on radiographic examination.

Ultrasonographic evaluation of the pastern region is helpful in identifying abnormalities associated with the soft tissue structures⁴ and is discussed in detail in Chapters 16 and 82.

Magnetic resonance imaging (MRI) of the pastern region is indicated in horses that have pain localized to the pastern region without radiological or ultrasonographic evidence of disease and may reveal soft tissue, bone, and/or cartilage

pathology.⁵ A more detailed discussion of MRI is found in Chapter 21. Benign osseous cystlike lesions are identified more commonly with MRI than with radiology in the proximal and middle phalanges but are frequently not associated with pain and lameness, and their significance should not be overinterpreted.

Nuclear scintigraphy is useful in identifying incomplete fractures of the proximal phalanx. Incomplete fractures of the proximal articular margin of the proximal phalanx can occur in all breeds, but they are most commonly seen in Standardbred (STB) and Thoroughbred (TB) racehorses. Clinical signs and response to perineural analgesia vary. Nuclear scintigraphy should be considered to eliminate fracture in horses with lameness referable to the fetlock and clinical signs consistent with an incomplete fracture of the proximal phalanx. Nuclear scintigraphy can be helpful to identify bone modeling in the early phases of OA of the PIP joint. Other bone-related abnormalities in the pastern region often are evident radiologically, and scintigraphy is unnecessary.

BREED PREDILECTION

Differential diagnoses of disorders of the pastern region of all breeds include OA, osteochondrosis, fractures, and infection. The types of fractures tend to be specific to breed or use. Fractures of the proximal phalanx occur most often in racing breeds, with the STB most often affected. Fractures of the middle phalanx occur most commonly in horses used for Western-type activities, such as reining, but are seen in all breeds during lunging or after kicks. Osteochondrosis of the proximal aspect of the proximal phalanx is common in yearling and 2-year-old TB and STB horses. Osteochondrosis of the distal aspect of the proximal phalanx and proximal aspect of the middle phalanx is less common with no breed predilection. OA of the PIP joint occurs most often in older horses used for riding or Western-type activities. It may be seen in young horses secondary to osteochondrosis.

FRACTURES OF THE PROXIMAL PHALANX

Fractures of the proximal phalanx are important causes of lameness in all breeds. Racing breeds are particularly prone. Clinical signs vary from subtle to obvious. In horses with complete fractures, lameness is severe, and limb swelling and deformity may be present. In horses with incomplete fractures, lameness may be subtle, and careful clinical and radiographic examination may be necessary to define the fracture. Serial radiographs may be needed to detect radiolucency and callus formation associated with short incomplete fractures of the proximal phalanx. Nuclear scintigraphy may be helpful.

Fractures of the proximal phalanx include the following types:

- Short and long incomplete sagittal fractures
- Complete fractures that exit the lateral cortex
- Simple complete fractures
- Moderately comminuted fracture
- Severely comminuted fracture
- Dorsal frontal
- Proximal palmar/plantar avulsion fractures associated with the collateral ligament
- Fracture of the proximal physis

Incomplete fractures of the proximal phalanx occur most commonly in racing breeds, but are also seen in sports and endurance horses. Clinical signs include mild to severe lameness. Fetlock joint effusion and mild swelling and pain over the dorsal aspect of the proximal phalanx are common but may not be present. Most fractures are readily identified radiologically, but in some horses dorsopalmar/plantar images that are slightly oblique to the sagittal plane are useful. In addition, obtaining follow-up radiographs 7 to 10 days after the fracture allows time for osteoclastic resorption along the fracture line to occur so that the fracture line becomes more obvious. However, there are some incomplete sagittal fractures that occur midway between the dorsal and palmar cortices of the proximal phalanx that may never be detectable radiologically and can only be identified using MRI or CT. Treatment of horses with incomplete sagittal fractures includes stall rest or internal fixation, depending on the degree of lameness, concern about catastrophic fracture of the bone, and economic factors. The advantages of surgical repair are well documented, but horses with incomplete short fractures of the proximal aspect of the proximal phalanx can often be managed with rest alone. In some circumstances a bone screw is placed to provide compression for short fractures to reduce the risk of fracture recurrence. Indications for internal fixation of incomplete fractures include fractures that extend more than 15 mm from the proximal articular surface, those with potential for catastrophic failure, and those that occur in horses with severe lameness. Internal fixation is accomplished by placement of 4.5- or 5.5-mm cortex bone screws in lag fashion. Although 4.5-mm screws generally are used and provide ample compression, 5.5-mm cortex screws have greater pull-out strength compared with 4.5-mm cortex screws in dense bone.⁶ However, the 5.5-mm cortex screws can be used to replace a stripped 4.5-mm thread. In a nondisplaced fracture, open reduction is not required, and the screws can be placed through minimal incisions. Arthroscopic examination of the dorsal and palmar/plantar aspects of the joint is recommended to evaluate articular cartilage and identify and treat additional abnormalities if present. Although most incomplete sagittal fractures of the proximal phalanx are simple, occasionally there is a transverse component, and radiographs should be examined carefully, especially when lameness is severe. Horses with incomplete fractures are reported to have a 67% to 89% chance to return to racing soundness after treatment. However, STBs returned to racing with slower racing times and reduced performance indices.⁷⁻⁹

Horses with complete fractures of the proximal phalanx are candidates for internal fixation to provide anatomical reduction and compression of the articular surfaces, improved comfort, reduced risk of OA, and early return to use. In horses with acute, minimally displaced fractures, reduction may be achieved by percutaneous placement of bone reduction forceps under radiographic or arthroscopic guidance. Open reduction, arthrotomy, or both may be required in horses with moderately to severely displaced fractures, chronic fractures, or fractures in which fragments of bone prevent reduction of the fracture fragments. After debridement of the fracture bed and reduction of the fracture, compression of the fracture fragments is accomplished using 4.5- or 5.5-mm cortex bone screws. External coaptation with a half-limb cast may be required for recovery

Fig. 35-1 • Lateromedial radiographic image of a Thoroughbred weanling with a Salter-Harris type II fracture of the proximal physis of the proximal phalanx. The horse was treated by application of a cast for 6 weeks; follow-up radiology after cast removal revealed healing of the fracture and normal alignment of the digit.

from general anesthesia or the immediate postoperative period. Prognosis for horses with noncomminuted complete fractures depends on whether the PIP joint is involved. Horses with fractures that enter the PIP joint had an approximately 50% chance to return to racing. Of those with complete fractures that exited the lateral cortex, 71% returned to racing.⁷⁻⁹

Salter-Harris type II fractures of the proximal aspect of the proximal phalanx occur in foals and weanlings (Figure 35-1). Reduction of the fracture is accomplished with the horse under general anesthesia. Methods of coaptation include bandaging alone, bandaging with splinting, or half-limb cast application. I prefer to use a cast for 4 weeks, but it is important that the cast be changed at 2 weeks. Other clinicians prefer less aggressive coaptation because of concerns of flexor laxity and osteoporosis of the PSBs. One of the Editors (MWR) prefers internal fixation of Salter-Harris type II fractures in foals because of this concern. Techniques include the placement of 3.5- or 4.5-mm bone screws in lag fashion from the metaphyseal component (usually palmarolateral/plantarolateral) in a dorsomedial direction or use of a small bone plate applied to the dorsomedial aspect of the proximal phalanx, using the tension band principle for repair. Rigid internal fixation mitigates the need to use prolonged external coaptation (see Figure 41-7).

Dorsal frontal fractures of the proximal aspect of the proximal phalanx occur in three general types: incomplete proximal dorsal articular fractures, complete proximal dorsal articular fractures, and fractures that originate in the midportion of the proximal articulation and extend distally into the proximal phalanx. Incomplete proximal dorsal frontal fractures occur most commonly in STB racehorses. The right hindlimb is most commonly affected.

Fig. 35-2 • Lateromedial radiographic image of a 12-year-old Thoroughbred mare with a large frontal plane fracture of the proximal phalanx of a forelimb. There is advanced preexisting osteoarthritis of the metacarpophalangeal joint. The fracture was repaired with 5.5-mm cortex screws in lag fashion and a cast applied for 6 weeks.

Proximal dorsal articular fractures can be treated with rest alone or internal fixation with a 3.5-mm cortex bone screw. The prognosis for horses with proximal fractures is good.¹⁰ Horses with large fractures that originate in the central portion of the metacarpophalangeal or metatarsophalangeal joint need internal fixation to preserve joint integrity, even if intended for only pasture or breeding soundness. In my experience, OA tends to be preexisting or develops despite anatomical reduction and internal fixation of the fracture, and the prognosis for athletic soundness is poorer (Figure 35-2).¹¹ The 5.5-mm cortex screws, which have a greater resistance to bending, are recommended because there may be larger bending forces in these fractures compared with sagittal plane fractures.

Horses with comminuted fractures of the proximal phalanx have acute, non-weight-bearing lameness and often limb deformity. Appropriate first aid is required to prevent further injury to the soft tissues and the digital arterial blood supply. A half-limb cast with a dorsally incorporated splint is appropriate to realign the bony column for transport to a surgical facility. Comminuted fractures can be divided into two categories for treatment: those with and those without an intact column (strut) of bone extending from the proximal to distal articular surfaces. An intact strut of bone allows reconstruction of many comminuted fractures of the proximal phalanx by lag screw fixation of the fracture fragments to the strut.¹² Treatment strategies include the following:

- Complete reconstruction via bone screws, plates, or both by open reduction
- Partial reconstruction and transfixation cast or external fixator
- Transfixation cast alone
- Use of external skeletal fixation (see Chapter 87)

In my opinion, the use of half-limb casts alone is not the best method of sole treatment for most horses with comminuted fractures of the proximal phalanx, although successful outcomes have been reported. Half-limb casts significantly reduce axial loading in the intact skeleton, but the risks of fracture compression, skin injuries leading to open fractures, and contralateral limb laminitis are substantial.^{13,14} The use of transfixation casts for management of these fractures has been reported. Based on the relatively poor outcome for comfort, some attempt at reconstruction of the fracture is recommended when possible.¹⁵

Horses with comminuted fractures with an existing strut of bone are candidates for open reduction and reconstruction with bone screws. An initial study reported an unacceptably high risk of infection after open reduction and internal fixation,¹⁶ but a more recent report described a good prognosis for pasture soundness.¹² If the strut has a transverse fracture but enough bone stock proximal and distal to the transverse fracture, then reconstruction of proximal phalanx fractures with two 4.5-mm narrow dynamic compression or locking compression plates and bone screws is advised. With both screw fixation alone and plate and screw fixation, external coaptation with a half-limb cast is required. Partial reconstruction of the articular surfaces and placement of a transfixation cast or external fixator is elected in horses with severely comminuted fractures to reduce degenerative changes, improve short- and long-term comfort, and reduce the requirement for subsequent arthrodesis. A transfixation cast is used when comminution is severe enough to prevent anatomical reconstruction and protection of the fracture from collapse is required. Transfixation casts have been shown to significantly improve axial stability compared with standard casts in an osteotomy model.¹⁷ External fixators are used in place of transfixation casts if the fracture is open to allow direct access to the injury site (see Chapter 87).¹⁸ The use of transfixation casts and external fixators carries the risk of catastrophic failure of the third metacarpal (metatarsal) bone and prolonged healing; the overall prognosis for salvage is only fair.¹⁵

Palmar/plantar avulsion fractures of the proximal phalanx usually occur after kicks, falls, or stall injury (Figure 35-3). Lameness is variable, and fetlock effusion is usually present. Differential diagnosis includes fracture and osteochondritis dissecans fragmentation. Because this region is the distal attachment for the collateral ligaments, surgical treatment is recommended to improve bony union and prevent OA. Treatment options include lag screw fixation, with one or preferably two 3.5-mm cortex bone screws. Surgical removal is also possible for chronic or small fractures or those that cannot be properly reduced. After removal or repair, external coaptation for recovery from general anesthesia and then for an additional 4 weeks is recommended. The prognosis is considered good with either treatment in the absence of OA.

DORSAL OSTEOCHONDRAL FRAGMENTS IN THE METACARPOPHALANGEAL/METATARSOPHALANGEAL JOINT

See Chapters 36 and 42 for a discussion of dorsal osteochondral fragments in the metacarpophalangeal/metatarsophalangeal joint.

Fig. 35-3 • Dorsolateral-plantaromedial oblique radiographic image of a metatarsophalangeal joint of a 2-year-old Standardbred colt. There is an avulsion fracture of the proximal plantarolateral aspect of the proximal phalanx. The fracture was stabilized with two 3.5-mm cortex screws placed in lag fashion.

OSTEOCHONDROSIS OF THE PROXIMAL INTERPHALANGEAL JOINT

Osteochondrosis of the PIP joint is less common than that of the metacarpophalangeal or metatarsophalangeal joints. As with other sites, osteochondrosis involves fragmentation (osteochondritis dissecans) or osseous cystlike lesions. Sites include the distal aspect of the proximal phalanx and proximal aspect of the middle phalanx. The radiolucent area at the distal central aspect of the proximal phalanx is a normal finding and represents the space between the lateral and medial condyles of the distal aspect of the proximal phalanx. Radiolucent areas or fragmentation in the condylar regions of the distal aspect of the proximal phalanx tend to cause clinical signs. In the most severe circumstances, these subchondral radiolucencies in weight-bearing portions of the joint may cause substantial OA and lameness requiring arthrodesis of the PIP joint. Osseous cystlike lesions are more common in the hindlimb than in the forelimb and can occur bilaterally. Osseous cystlike lesions can communicate with the PIP joint, and if lameness is present, radiological evidence of OA can be substantial. Subtle clinical signs often are seen in horses with osseous cystlike lesions that do not communicate with the PIP joint. Although unusual, sudden-onset severe lameness can occur as a result of osseous cystlike lesions even though the radiological abnormality was present for several months or years. Clinical relevance of osseous cystlike lesions must be established using diagnostic analgesia, and in some horses scintigraphy is required. Management of horses with osseous cystlike lesions may include intraarticular injections or arthrodesis of the PIP joint in some horses. Arthrodesis of the PIP joint can yield a good prognosis for soundness in Western performance horses or other types of sports horses that are not expected to perform at advanced levels. A periarticular drilling procedure can be used in horses with osseous cystlike lesions that do not

communicate with the PIP joint. A small drill bit is used under radiographic or fluoroscopic guidance to approach the cystic cavity. Methylprednisolone acetate, expanded stem cells, or liquid bone marrow can be injected. Alternatively, cancellous bone can be packed into the cyst cavity. Radiological evidence of healing of the cyst cavity is variable, and in some horses residual lameness remains.

Osteochondral fragments associated with osteochondrosis tend to occur at the palmar/plantar eminence of the proximal aspect of the middle phalanx and cause variable lameness. They often are an incidental finding found on radiographs acquired before sale, but they certainly can complicate the sales process. Prognosis is difficult to assess in yearlings that have not been trained. Osteochondrosis fragments are more common in hindlimbs than in forelimbs. In adult horses there may be radiological evidence of advanced OA, even if lameness is mild. Because these fragments can be difficult to remove, it is important to document the true source of lameness before surgery is considered. Arthroscopic techniques for the pastern have been described and are most commonly used for dorsal fragments. Palmar/plantar fragments can be accessed arthroscopically or removed via arthrotomy, which may be preferable for large fragments (see Chapter 23 and Figure 23-1).^{19,20}

OSTEOARTHRITIS OF THE PROXIMAL INTERPHALANGEAL JOINT

OA of the PIP joint is also known as *high ringbone*. Horses used for jumping, dressage, and Western-type activities seem to be prone to high ringbone. It can also be a consequence of articular fracture, infection, or osteochondrosis. The clinical signs of OA of the PIP joint include mild to severe lameness. Lameness is exacerbated by distal limb flexion. Obvious bony formation or angular deformity may be present in horses with advanced lameness. Diagnosis is based on clinical signs, response to perineural or intraarticular analgesia, and radiological findings. Radiological abnormalities commonly include periarticular new bone formation, subchondral bone increased radiopacity, and loss of joint space typically on the medial aspect of the PIP joint. However, small dorsal periarticular osteophytes are a frequent incidental radiological abnormality and are not necessarily of clinical significance. Angular deformity is typically only present in horses with advanced OA resulting from collapse of the joint surface typically on the medial side. Comparative radiographs of the contralateral limb should also be obtained because the condition may be bilateral. Pain associated with the PIP joint may be present without any radiological signs of OA, and scintigraphic examination is useful in documenting active bone modeling. On the other hand, horses may develop acute severe lameness with radiological evidence of existing OA that predated any clinical evidence of pain. Lameness improves after perineural or intraarticular analgesia.

In horses with mild OA of the PIP joint that is unrelated to fracture, conservative treatment includes therapeutic shoeing aimed at reducing the toe length and elevating the heel and easing breakover in some horses. Nonsteroidal antiinflammatory drugs are useful. The therapeutic value of administering intramuscular glycosaminoglycans and intravenous hyaluronan is questionable. Intraarticular

injections are of considerable value. A combination of hyaluronan and corticosteroids or corticosteroids alone are most effective in horses with mild or moderate OA. However, in horses with advanced OA, particularly those with extensive periarticular new bone proliferation and extensive loss of joint space, arthrodesis should be considered. The surgical procedure is invasive and expensive but is generally considered a better solution over the long term. Natural ankylosis of the PIP joint can occur, but it is a long, painful process and one that is not necessarily complete. Surgical arthrodesis is best. Tibial neurectomy can be helpful in horses with advanced hindlimb proximal interphalangeal OA that are not meant to resume athletic careers.²¹

ARTHRODESIS OF THE PROXIMAL INTERPHALANGEAL JOINT

Arthrodesis of the PIP joint is indicated in horses with advanced OA or an articular fracture. Lag screw fixation of simple fractures can be performed, but because of difficulty in obtaining anatomical reduction of the PIP joint surface and resisting tension forces at the palmar/plantar eminences, lag screw fixation alone is usually unsuccessful in preventing OA and returning horses to athletic soundness. Therefore I recommend PIP joint arthrodesis in horses with articular fractures.

Many methods of arthrodesis of the PIP joint are described, and opinions vary as to which is preferred. Current preferred methods involve the insertion of three parallel 4.5- or 5.5-mm screws or dorsally applied plate or plates with additional transarticular screws. I have used both methods and prefer the plating technique because when compared with screws alone it improves comfort in the immediate postoperative period as a result of increased biomechanical stability and reduces the necessity for prolonged cast application. This method requires cast coaptation for 2 to 3 weeks to protect the incision site. The plating technique provided improved stability compared with the three 5.5-mm parallel screw technique in fatigue testing.²² After arthrodesis of the PIP joint with screws alone, approximately 80% to 89% of horses with hindlimb and 46% to 80% of horses with forelimb lameness returned to athletic soundness.²³⁻²⁵ Long-term follow-up data for the plate/screw technique revealed 81% of horses with forelimb and 95% of horses with hindlimb arthrodesis were able to resume performance careers.²⁶ The locking compression plate (LCP) has been recently advocated for arthrodesis of the PIP joint, and its new design with the Combi hole at one end avoids the long pointed end interfering with the extensor process of the distal phalanx. Long-term follow-up data regarding the use of LCP/screw technique for pastern arthrodesis are not yet available.

Horses with comminuted middle phalanx fractures (Figure 35-4) or those that involve the distal interphalangeal (DIP) joint should undergo arthrodesis of the PIP joint with single or double plating and potentially transfixation casts or external skeletal fixation (see Chapter 87). Comminuted fractures of the middle phalanx should be repaired if possible to preserve the DIP joint surface and, if possible, the PIP joint surface. Displacement of the distal articular surface considerably worsens prognosis. Single or double

Fig. 35-4 • Lateromedial radiographic image of the left hindlimb of a 7-year-old Thoroughbred-cross gelding with a comminuted articular fracture of the middle phalanx. The radiograph was obtained through a distal limb cast. The fracture was repaired using two 4.5-mm narrow dynamic compression plates and 5.5-mm cortex screws, with arthrodesis of the proximal interphalangeal joint. The gelding returned to competitive jumping.

plating can be used depending on the configuration of the fracture. The use of additional screws placed in lag fashion is usually required to reduce large fragments and reconstruct the articular surface. Another plate technique using a Y-plate has been tested experimentally and shows similar biomechanical properties to the double-plate technique.²⁷ Cast coaptation is required for 6 to 8 weeks after surgery. Transfixation pins are used to prevent collapse of the fracture in horses with severely comminuted fractures. This technique may be combined with plate and screw fixation. Prognosis after double-plate fixation of 10 horses with comminuted fracture of the middle phalanx was good for pasture soundness, and 5 horses were able to be ridden or shown, but mild lameness persisted.²⁸

BONE TRAUMA

Since the advent of MRI, one of the Editors (SJD) has recognized horses with acute-onset severe lameness associated with pain in the pastern region in the absence of detectable radiological abnormality in the acute stage. These horses have had evidence of primary osseous pathology characterized by focal or diffuse areas of increased signal intensity in fat-suppressed images and reduced signal intensity in T1-weighted images, consistent with bone edema, fibrosis, or necrosis. Some horses have made a slow but spontaneous recovery, whereas others have subsequently developed radiological evidence of OA of the proximal or DIP joints associated with persistent lameness.²⁹⁻³¹

SOFT TISSUE INJURIES

Soft tissue injuries in the pastern are discussed in Chapter 82.

SUBLUXATION OF THE PROXIMAL INTERPHALANGEAL JOINT

Subluxation of the PIP joint is uncommon and can occur in the palmar/plantar direction or dorsally. Palmar/plantar subluxation usually is seen after severe, traumatic soft tissue injury, such as complete tearing of the distal sesamoidean ligaments, SDFT branch injury, or a combination of soft tissue injuries or fracture. Treatment options for palmar/plantar subluxation include both conservative and surgical management. External coaptation can be successful in adult horses managed acutely. The application of a Kimzey splint (Kimzey Leg Saver Splint, Kimzey, Inc., Woodland, California, United States) is an excellent method of first aid for this injury. Cast immobilization can be successful, but instability of the PIP joint may preclude successful realignment with this method. Arthrodesis of the PIP joint is always an option. Dorsal subluxation can occur after traumatic disruption of the suspensory apparatus and arthrodesis of the fetlock joint to manage this problem, but it most commonly occurs in horses with progressive, severe suspensory desmitis. This is particularly true in the STB or TB racehorse, in which suspensory desmitis is common. Swelling along the dorsal aspect of the pastern region is the first clinical sign recognized, but progressive hyperextension (dropping) of the fetlock joint is usually present. The appearance of dorsal subluxation in any horse with chronic suspensory desmitis is a negative prognostic sign. Dorsal subluxation may also occur in association with transection of a branch of SDFT, severe injuries of the oblique sesamoidean ligaments, or rupture of the straight sesamoidean ligament. In these horses there is usually no associated hyperextension of the fetlock.

Chronic injuries of the oblique or straight sesamoidean ligaments may be associated with dorsal extension of the dorsal articular margins of the PIP joint, presumably a response to low-grade instability of the joint.^{3,29} This is not synonymous with OA. Although radiological abnormalities may be obvious, such changes are not necessarily associated with pain and lameness.

Dorsal subluxation of the PIP joint can occur without any identifiable structural abnormality of the pastern or metatarsal soft tissue structures. This occurs primarily in the hindlimbs in young horses, and lameness is usually absent or mild. Dorsal subluxation is most often dynamic in nature and resolves during full weight bearing. The presence of changes consistent with OA worsens prognosis. Dorsal subluxation of the PIP joint as a result of mild flexor deformity was reported in three horses. In these horses, ranging in age from 5 months to 4 years, subluxation was believed to be caused by mild contraction of the deep digital flexor tendon (DDFT) without compensatory contraction of the SDFT. Subluxation was seen primarily during early weight bearing, but the condition resolved during full weight bearing. Tenotomy of the medial head of the DDFT in the proximal metatarsal region resolved dynamic dorsal subluxation.³²

WOUNDS AND INFECTION IN THE PASTEREN REGION

Lacerations and puncture wounds in the pastern region have a high propensity to involve the PIP joint or DFTS.

Careful inspection of the wound, radiography, ultrasonography, and analysis of synovial aspirates are often required to determine the extent of the wounds. Wounds that involve the PIP joint or DFTS require aggressive management to prevent synovial infection. Treatments include synovial lavage, wound debridement, drain placement, and systemic and regional antimicrobial therapy with or without tenoscopic examination. Intrasynovial, systemic, and regional perfusion of antimicrobial agents can be used. Sequelae of PIP joint infection include OA. Sequelae of infection of the DFTS include intrasynovial adhesion formation and infectious osteitis of the PSBs (see Chapters 72 and 74).

Infectious disorders of the pastern region can be caused by injuries or hematogenous spread of bacteria, particularly in young horses. Although this chapter is not meant to be a discussion of the treatment of infection, it is important to point out some things of note. Serial radiography, ultrasonography, and MRI are useful for determining the location and extent of the infectious process. Determination of the actual structure involved can be challenging in the pastern region. Regional perfusion of antimicrobial agents is particularly useful in the pastern region to combat infection. Tissue levels can reach as high as 30 times and synovial levels up to 100 times the minimum inhibitory concentration for up to 24 hours after regional perfusion.³³ Even horses with obvious bone involvement from infectious phytitis/arthritis can be treated successfully with systemic and regional antimicrobial agents and lavage (Figure 35-5).

Fig. 35-5 • Dorsoplantar radiographic image of a 3-month-old Thoroughbred colt with infectious arthritis/epiphysitis of the proximal aspect of the middle phalanx. Medial is to the left. Note the well-circumscribed radiolucent area in the proximomedial aspect of the epiphysis. The foal was treated with joint lavage and regional perfusion of the digit with antimicrobial agents and made a complete recovery. Presale radiographs obtained 1 year later revealed no detectable radiological abnormality.

Chapter 36

The Metacarpophalangeal Joint

Dean W. Richardson and Sue J. Dyson

ANATOMICAL CONSIDERATIONS

The metacarpophalangeal (fetlock) joint is an intensely loaded, high-motion joint that is frequently injured in athletic horses. Fetlock region lameness can occur in horses of any occupation, but the joint is at particularly high risk in horses performing at maximal speed. Countering the high load experienced by the joint is the elastic suspensory apparatus that constrains the range of extension. Both the superficial and deep digital flexor muscle tendon units additionally serve to actively support the fetlock joint because of their position on the palmar aspect of the joint. Loss of this active support by the digital flexor tendons may lead to overload of the suspensory apparatus support and some degree of hyperextension. Extreme extension of the metacarpophalangeal joint results in impingement of the proximal rim of the proximal phalanx against the dorsal aspect of the third metacarpal bone (McIII), high compressive forces on the distal, palmar aspect of the McIII opposing the proximal sesamoid bones (PSBs), and both tensile and bending forces on the PSBs intercalated within the suspensory apparatus.¹ Complex forces of torsion on the loaded fetlock joint result in a myriad of injuries.

The metacarpophalangeal joint is anatomically composed of the distal aspect of the McIII, the proximal phalanx, and both PSBs. A single synovial space extends on its palmar aspect at least 3 cm proximal to the apex of the PSBs. Dorsally, a bilobed synovial “pad” is located on the proximal dorsal articular rim of the distal aspect of the McIII; this pad presumably functions to help cushion the impingement of the McIII and proximal phalanx. The ligamentous elements of the fetlock joint are complex and important. Well-developed medial and lateral collateral metacarpophalangeal and metacarposesamoidean ligaments constrain the almost purely sagittal motion of this joint, but both abduction and rotation occur.² The suspensory branches insert on the proximal, palmar abaxial margins of the PSBs and functionally continue through the distal sesamoidean ligaments to attach the distal portion of the PSBs to the proximal phalanx (cruciate or deep and oblique or middle) and the middle phalanx (straight or superficial). The intersesamoidean ligament attaches the axial aspects of the PSBs.

The digital flexor tendon sheath and its contents are described elsewhere (see Chapter 74). The common digital extensor tendon is unsheathed as it passes over the dorsal aspect of the joint. Branches of the medial and lateral palmar and metacarpal nerves primarily supply innervation to the fetlock joint,³ but small subcutaneous branches of the ulnar nerve supply a minor amount of dorsal sensory innervation.

DIAGNOSIS
